DR. E. L. PARTRIDGE, from a clinical standpoint, suggested that possibly the early appearance of menstruation might lead to the early ossification of the bones of the pelvis, and therefore might be of some assistance in forming an opinion with reference to its general condition. Again, it should be borne in mind, in endeavoring to arrive at an opinion as to whether a difficult first labor is likely to be succeeded by labors equally difficult and perhaps dangerous, that the first labor is frequently severe, perhaps necessitates craniotomy, and yet subsequent labors are comparatively easy. This can be explained by the fact that ossification of the child's head is more complete in primiparæ than in multiparæ, and therefore the head less yielding. Practically he had found that the cephalotribe applied to the delivered head had facilitated delivery of the shoulders. He believed that the equally contracted pelvis should receive more consideration and study than simple cases of deformed pelvis from disease, because it probably occurred far more frequently, and it was very probable that craniotomy and cephalotripsy were performed more frequently in this class of cases than in any other.

DR. H. J. GARRIGUES thought there was no doubt that diagnosis could be made during pregnancy. Of the external methods to be employed, he thought Baudelocque's instrument offered the most advantages. Internal pelvimetry was difficult to practise, but it might be assumed that if the finger could touch the promontory of the sacrum the pelvis was contracted. In cases in which operative interference was necessary he thought the following should be considered in the order mentioned: first, gastro-elytrotomy; second, Cæsarian section, not according to the old method but according to the methods recently described in monographs; third, Porro's operation; fourth, total extirpation of the uterus.

The PRESIDENT directed attention to one important practical point on which we are all liable to be consulted. It had already been alluded to by the author of the paper, namely, that external conformation, form and figure and size of the patient offered but slight indication of the condition of the pelvis. This is a point which should be constantly borne in mind. He had repeatedly had patients under five feet two inches in height, who had a perfectly normal pelvis, and had given birth to fine, healthy, and often large children. Again, those patients who have had antero-posterior and lateral curvature of the spine, perhaps also hip-joint disease, have experienced no difficulty whatever in the process of parturition. In some cases he had been able to form a pretty accurate estimate of the probable diameters of the pelvis, but not

always, and oftentimes it was found quite impossible. He then referred to a case in which the woman had suffered from double curvature of the spine and also hip-joint disease in early life, and in whom he was unable to discover any deformity of the pelvis whatever, and she gave birth to a child weighing ten pounds and a half before her attending physician could reach her. The President also referred to a case of an exactly opposite character, in which a large, well-developed woman had so small a pelvis that it was with the utmost difficulty that she could be delivered of a child not very far advanced in development. Notwithstanding the proximate estimate which we might be able to make in certain cases concerning the diameters of the pelvis, he regarded it important to be extremely cautious with regard to promising favorable results during parturition even after having made a most careful and thorough examination.

In closing the discussion, DR. TAYLOR briefly alluded to the equally contracted pelvis from a gynecological standpoint, and expressed the opinion that very many cases of uterine displacements were due to this peculiar condition of the pelvis rather than to disease of the uterus itself.

The Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 14, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. A. G. GERSTER presented, in behalf of a candidate, a specimen of

SARCOMA OF THE JAW.

DR. B. A. WATSON presented a specimen of

STENOSIS AND ATRESIA OF THE PULMONARY ARTERY, WITH AN OPENING IN THE VENTRICULAR SEPTUM.

Alexander A—, aged thirteen; born in Scotland; came to America in June, 1881; admitted to Christ Hospital May 2, 1882. According to patient's account, the cyanosis which later became a very marked symptom, was first noticed when he was four years of age, and appeared at the tips of the fingers, slowly extending over the hands and along the arms, later involving the lower extremities and finally the face and entire body. At the time of admission he was in a very exhausted condition, brought on by the fatigue and excitement of travelling the previous day and night from Birmingham, Conn., to Jersey City. Immediately after being put in bed, he became semi-comatose, in which condition he remained several days. On the fourth day (unable to take nourishment the three preceding days), and from that time till the end of the attack, he could be aroused sufficiently to take liquids, but would relapse into the former condition directly afterward. During the attack the cyanosis was extreme, being much more marked than at any other time, the pupils were widely dilated and insensible to light, the respiration slow and sighing, the pulse rapid and feeble (120 to 150), the temperature at first somewhat elevated (100° to 102° F.), but later slightly below the normal and the extremities cold and covered with a slight perspiration.

The patient gave no history of similar attacks prior to admission to the hospital, but had them at varying intervals subsequently. The later attacks were of less intensity and shorter duration, and were generally produced by slight fatigue or exposure to the heat of the sun. They were always preceded, for several hours, by severe headache and a general feeling of illness.

On the evening of the day before he died he complained of the usual symptoms of an impending attack, complicated by a severe pain in the precordial region, of which he had never before complained. He gradually became worse until he died, September 15th, at 10 A.M.

Physical examination.—Heart: Precordial area of dulness not increased and apex-beat in normal position, but on auscultation two murmurs were heard at the apex,

supposed to be mitral direct and regurgitant, and two at the base, supposed to be aortic direct and regurgitant. The lungs, when the patient was not in the semi-comatose and deeply cyanosed condition, were normal, but during the bad spells subcrepitan râles were heard over the entire chest.

Post-mortem examination.—Heart: Abnormally large (weight not known), left auricle one-half the capacity of the right, tricuspid and mitral valves perfect, and aortic valves atheromatous, covered with vegetations, two of them being joined together by a material of cartilage-like firmness. There was also found to be marked stenosis and atresia of the pulmonary artery, with an opening in the ventricular septum, which permitted the little finger to be easily passed into it. The left common carotid artery arises from the innominate and the left subclavian nearer the median line than in a normal body.

Remarks.—The principal interest connected with this specimen centres in the stenosis and atresia of the pulmonary artery, inasmuch as the interventricular opening and valvular lesions are probably dependent on the arterial obstructions.

The symptoms observed and fatal termination are in harmony with our published records; but, these cases are not of such frequent occurrence as to be therefore uninteresting.

DR. WATSON also presented specimens with the following history:

COMPOUND FRACTURE OF THE LEFT TIBIA—NON-UNION—
SUBSEQUENT AMPUTATION OF THE LEG.

August M—; born in Germany; aged twenty-six; laborer, admitted August 26, 1882. This injury had been produced by indirect force, and examination showed an oblique fracture in the middle of the tibia, the lower segment of which had been driven through the integument covering the anterior surface of the bone.

The patient was fully anesthetized and reduction attempted, but it was not accomplished; the soft parts were then thoroughly divided, and another thorough but unsuccessful attempt made at reduction, after which, both the lower and upper segments were exposed and sawn smoothly off. There was removed by this operation about three-fourths of an inch of bone, but nevertheless after the reduction it was found that the sawn surfaces remained in actual contact. A drainage-tube was introduced and the wound neatly closed with iron-wire sutures. The entire operative procedure was performed under strict antiseptic precautions.

August 27th, the patient was comfortable, but the pulse and temperature were above the normal. The temperature reached on the third day 104° F., although the patient was still comfortable; but from this date the temperature gradually declined, and before the end of the month his condition was normal in every respect. August 31st, the sutures were removed and the wound was found to be completely healed externally, except at the points where the drainage-tube made its exit. During the month of August the wound-fluids discharged, although not profuse, were sufficient to soil the dressings and make a daily change necessary. The removal and reapplication of these dressings were made under strict antiseptic precautions until September 1, 1882, when all Listerism was immediately discontinued.

There is a complete break in the history of this patient during the next four months, with the exception that he was transferred to the Jersey City Charity Hospital, November 2d, at which time his condition was designated in the books of St. Francis by the word "unimproved."

The amputation was performed in the Charity Hospital, January 5, 1883, after which the patient made a good recovery.

The pathological specimen exhibits at the point of the fracture a progressive necrosis which involves a portion of both fragments. There is also observed to the outside of the upper fragment a new bony formation which

is one and one-fourth inch in width, one-fourth thick, and one and three-fourths long, which passes down and overlaps the lower fragment one-fourth of an inch. This new bony formation has evidently been fractured near its attachment to the lower fragment, since its fractured surfaces were covered with a layer of firm fibrous material. This fracture, it is thought, occurred soon after the new material had attained its present dimensions. The original fragments are separated elsewhere by an irregular cavity surrounded by diseased bone. This separation at no point exceeds half an inch, and is shown to be due to the erosion of the diseased bone, while at other points still in actual or almost actual contact. There were several ligamentous bands which connected the original fragments together, but these have disappeared during the process of cleaning.

DR. WATSON remarked concerning the second specimen that the necrosis was due unquestionably to the accumulation and decomposition of pus, and that if he had been able to avoid this, union would probably have taken place. The question therefore arose, what should be done under such circumstances? Would it have been better to have excised the diseased portions of tibia, leaving as much of the periosteum as possible? or, would it have been better to have excised not only the diseased portion of the tibia, but the corresponding portion of the fibula? or, would it have been better to have removed the necrosed portion of the bone, and afterward attempted bone-grafting, an operation which he had never adopted and in which he had never had any experience?

DR. PUTNAM-JACOBI said that Dr. Watson's second case was also interesting because it illustrated the existence of the antiseptic traumatic fever to which attention had been called in an elaborate monograph recently published in Volkmann's series. The writer had collected a number of cases in which operations had been performed under strict antiseptic precautions, and afterward the patients had a very high temperature; but without any conscious disturbance of their well-being. Dr. Jacobi remarked that Dr. Watson's first specimen illustrated the statement which had been made, that as a clinical fact malformations of the heart can be almost entirely summed up in stenosis of the pulmonary artery; as this alone, or with its consequence—patency of the inter-ventricular septum, is almost certain to occasion clinical symptoms. It did not appear, however, in the history of Dr. Watson's case, that the openings in the septum had given rise to any symptoms, and so far sustained a very elaborate article written to prove that the opening in the auricular septum may persist without giving rise to physical signs or rational symptoms of cardiac disturbance.

DR. WATSON remarked that he was unable to obtain any history of preceding inflammatory attacks or any special cardiac disturbance.

CHRONIC OSTEOMYELITIS OF THE LOWER PART OF THE
FEMUR.

DR. A. G. GERSTER presented a specimen removed from a female child, ten years of age, who became seriously ill during the course of last August, with symptoms which led the family physician to make the diagnosis of cerebro-spinal meningitis. The child was in a comatose condition, had strabismus and convulsions, and in the course of the second week very high fever developed, and he noticed marked swelling of the lower third of one thigh. Dr. Gerster saw the child in consultation, and at once recognized that he had to deal with acute osteomyelitis of the femur. At that time also distinct fluctuation was present, and other evidences of a deep-seated abscess were obtained. The tissues situated above the bone, and not distended by pus, were very much thickened as usual by cedema. He advised immediate incision, and as soon as it was made an enormous quantity of pus was evacuated, and the general condition of the child improved very considerably. At that time he had

not noticed any contraction of the joint, but from that date contraction of the knee-joint commenced to take place, and finally within two months and a half an angle of twenty to twenty-five degrees was attained. The slightest attempt at passive motion caused pain. An effusion into the joint could not be detected, and he suspected that the contraction on the knee was caused by the presence of a cheesy focus in the lower epiphysis, or by necrosis of a portion of the cancellous tissue. In the month of November he performed necrotomy of the femur. After making suitable incisions he endeavored to expose the diseased part, and tried to penetrate the central portion of the condyles in order to determine the exact state of affairs in that locality. The specimen exhibited a femur covered with a thick layer of newly formed bone which had disappeared from the posterior surface at the part corresponding to the *linea aspera*. It was at that place where he endeavored to reach the central portion of the bone by the use of chisel and mallet. He succeeded in doing so, and scooping away a large quantity of diseased bone, mostly fragments of small size, one, however, being three-fourths of an inch in length. No improvement followed the operation. The bone continued to increase in size, suppuration continued, contraction of the knee-joint persisted, the child's general state of health began to suffer more severely, the liver began to increase in size, albumen appeared in the urine, and he decided to amputate the limb and performed the operation two weeks ago. After having removed the limb he sawed the bone through longitudinally, and found the following condition of affairs. The knee-joint did not contain any effusion whatever, nor present any signs of acute inflammation, although one portion freely communicated with the cheesy focus situated in the condyle. He mentioned this fact for the reason that the question was raised as to whether it would not have been well to have treated the limb by *brissement forcé*. The condition of things, revealed on examination of the bone, explained why such an undertaking might have been followed by serious consequences. The cavity of the joint was intact, yet the disease was so close to it that if the limb had been forcibly stretched, undoubtedly the contents of this cavity would have been emptied into the joint and immediately established purulent infection. As it was, the anterior wall of the capsule being put on the stretch, was drawn snugly over the opening of the cheesy focus, thus preventing an escape of its contents into the joint-cavity as long as extreme flexion was maintained. The external condyle was the original seat of the disease where the acute osteomyelitis had taken place. There was a thick layer of new osseous tissue enclosing the original bone. He had therefore to deal with chronic osteomyelitis in the epiphysis and of the lower end of the shaft of the femur, chronic periostitis of the entire shaft of the bone, producing periosteal new formation of the bone throughout the entire length of the femur. The specimen was especially interesting on account of the fact that although the necrosis was only circumscribed and confined to the epiphysis, yet there was an enormous new formation of bony matter throughout the entire length of the shaft, such as is characteristic of extensive central necrosis.

VENEREAL WARTS.

DR. GERSTER presented specimens of venereal warts, accompanied by the following history: They were removed from a patient thirty-two years of age, who had no history of either hereditary or acquired syphilis. When he first saw the patient he found about the anal opening numerous masses of villous growths covering an area of about six square inches, which he recognized as venereal vegetations or papillomata that had acquired a very large size. Their origin was doubtful. One peculiarity of the growths was that they occupied two semilunar spaces about the anal opening, leaving the median

line of the perineum along the raphe entirely intact, a fact which he had never before observed. Four or five years ago he saw a mass of similar growths removed from the skin surrounding the anal opening in a patient under the care of Dr. D. M. Stimson, during his service at the Mt. Sinai Hospital, and Dr. Gerster recollected that in that case the mass was removed very thoroughly by means of the galvano-cautery. Yet it relapsed three or four times, finally involved the anal mucous membrane, and necessitated a very severe cutting operation, in which a portion of the mucous membrane of the rectum had to be removed. Bearing in mind that fact, he did not lose any time in attempts at cauterization, but excised the growths, together with their bases, and he hoped to secure non-recurrence of the disease. Microscopically the tumors were simply warts. The incisions healed by granulation in six weeks.

Dr. Gerster, in reply to a question, said that he did not attempt to secure union by first intention in his first case, and that the child at the present time is doing very well. There had not been any notable elevation of the temperature. In several cases of osteomyelitis, especially central, he had known of the diagnosis of typhoid fever having been made, and in this case the diagnosis of another severe systemic disease was made.

DR. J. LEWIS SMITH asked if there was much swelling of the limb in the early stage.

DR. GERSTER replied that there was not, and that the swelling developed in the course of two weeks.

DR. PUTNAM-JACOBI referred to a case lately seen in dispensary practice, a child four years of age, suffering from osteomyelitis of the upper extremity of the femur, accompanied by complete separation of the epiphysis. There was considerable swelling of the thigh and buttock, and the swelling extended into the groin and to a considerable extent upward upon the abdomen, so much so that the question was raised as to whether osteitis of the pelvic bones did not also exist. The necessity for opening the abscess was certainly apparent, but, owing to the delays incidental to dispensary practice, this operation was unfortunately not performed on the occasion of the child's visit. The subsequent history of the case was, that the child had a violent attack of pain in the abdomen, and the swelling of the thigh and buttocks collapsed. Simultaneously the child passed into collapse and died two hours afterward from what, so far as could be inferred from this report, was shock due to bursting of the abscess into the peritoneum. Probably if the physician who saw the child previous to the time it came under her observation, or if she herself had acted promptly, the child's life would have been saved.

DR. FERGUSON presented a specimen of

DISSECTING ANEURISM OF THE ARCH OF THE AORTA.

A man, aged fifty-six, native of England, and a news-dealer by occupation, on February 9, 1883, at 9 P.M., suddenly felt faint and became unconscious. He was immediately transferred by ambulance to the New York Hospital. A friend said that ten years ago the patient had a similar attack, followed by unconsciousness which lasted for two days, and that he was sick for six weeks, but that since that time he had been quite well. On admission he was semi-comatose, was fairly nourished, and there was no oedema. He could be aroused, seemed to understand, but could not answer. His heart action was slow and feeble. The apex-beat was in the sixth interspace on nipple line. The radial arteries were stiffened; the right radial artery was tortuous. The radial pulse was from fifty-eight to sixty-four per minute. The day after admission he was completely unconscious, his breathing became stertorous, and his pulse ran up to ninety per minute. His right pupil was slightly dilated, and there was slight paresis of the right side of the face, with slight left hemiplegia. He continued in this condition until the time of his death, three days after admission. His heart action was imperceptible for two hours before

he died. Urinary examination showed a small amount of albumen, hyaline and granular casts. His temperature was 102.6° F., respiration 30, and pulse varied from fifty-eight to ninety per minute. He was given carbonate of ammonia, digitalis, and whiskey. The autopsy revealed intense oedema and congestion of the lungs, chronic diffuse nephritis, and atheroma of the vessels at the base of the brain. The brain and membranes were otherwise normal. The liver was congested. The stomach and intestines were normal.

Heart.—The pericardium contained 680 c.c. of fluid and coagulated blood. The left ventricle was dilated, the left ventricular wall hypertrophied, and the muscular fibres of the heart contained a great deal of fat. The valves were competent; the anterior segment of the mitral was atheromatous.

Aorta.—The arch of the aorta, especially its ascending portion, was markedly dilated. There was a rent in the wall of the ascending portion, through the intima and media, commencing just above the aortic valve and extending directly upward an inch and a half. The middle and outer coats of the artery were separated almost throughout the entire extent of the vessel. The blood passing downward into the pericardium, upward to a considerable distance around the vessels given off from the arch and separating the middle and outer coats of the thoracic and abdominal aorta, down to the iliac vessels. The aorta throughout was atheromatous.

(To be continued.)

Correspondence.

THE PROTECTION OF COLLEGE STUDENTS FROM VENEREAL DISEASES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Referring to the editorial in THE MEDICAL RECORD of February 24th, on "The Protection of College Students from Venereal Diseases," it may be proper to state that the suggestion therein made as to the inculcation of continence, "directly, and not by spiritual generalities," has been anticipated at Cornell University. In following to its legitimate conclusion the urgent and often-expressed wish of President White for "practical instruction in the laws of health," I have for several years supplemented the regular courses in physiology and hygiene by one or two lectures to the Freshmen upon the advantages of continence and self-restraint, and the dangers, physical and mental, as well as moral, of sexual transgression. In addition, when requested by a majority of the class, I have given to the Seniors, just before graduation, advice with regard to the hygiene of the marriage relation, especially the tendencies to excess, and to a lack of consideration for the wife. While far from satisfied with either the extent or the character of this instruction, I have reason to believe that it has diminished the amount of undergraduate immorality, and contributed to the welfare of married alumni. Similar instruction is, I think, given at Amherst College, and I trust the time may come when college faculties will generally feel in some degree responsible for such errors of their students as might have been arrested by the impartation of adequate information and sound advice.

BURT G. WILDER, M.D.

ITHACA, N. Y., February 26, 1883.

THE CAUSE OF DIABETES.—Among 600 cases of diabetes treated by Dr. Richard Schmitz (*British Medical Journal*), 248 were in families in which diabetes had already disappeared, 96 were in neuropathic or psychopathic families, and in 183 cases the exciting cause of the disease was attributed to some acute disturbance of the nervous centres. In 153 cases the disease was attributed to an excessive indulgence in sugar.

New Instruments.

GRUNOW'S NEW CAMERA LUCIDA.

MR. J. GRUNOW, of this city, has constructed a new camera lucida, which deserves the attention of microscopists. It was described by the editor of *The American Monthly Microscopical Journal*, at a recent meeting of the New York Microscopical Society.

The instrument consists of three rectangular, equilateral prisms, so arranged that, when placed over the eyepiece with the microscope inclined, which is the most convenient position, a portion of the surface of the work-table of the size of about twelve by fifteen inches is projected into the field of view, so as to be distinctly and clearly seen together with the object on the stage.

The two prisms e, f, g , and h, f, g , are cemented together so as to form a cube, the sides h, g , and f, e , being parallel. The hypotenuse f, g , of the prism h, f, g , is silvered, to do away with the blue halo otherwise peculiar to this form of prism, which would greatly obscure the reflected image. The silver is removed at the centre of the coating, at the point o , so as to leave a clear space about half the diameter of the pupil of the eye. The other prism l, j, k , is placed with the side j, k , inclined to the cube h, g, f, e , at such an angle as may be most desirable.

In viewing the object under observation in the direction of N, M , through the aperture at o , we see the whole field of view, while at the same time the drawing-board and pencil are reflected from the side l, j , of the prism l, j, k , to the silvered surface f, g , and then reflected to the eye in the direction of P, N . Both the pencil point and the object are very clearly seen without any strain upon the eye.

It is in this respect that the maker claims for this camera lucida superiority to any other form. It can be immediately applied, while the microscope is in an inclined or vertical position, without any change of conditions or loss of time. The camera is simply slipped over the eyepiece, the paper placed on the table, and the drawing proceeded with.

THE WANDERINGS OF A SWALLOWED NEEDLE.—Dr. W. P. Beach, House-Surgeon of Randall's Island Hospital, N. Y., sends us an account of the following case: The patient, a woman forty years of age, four years ago swallowed an ordinary cambric needle about one and one-half inch long, from which she experienced no trouble until two weeks ago, when she felt a slight soreness just over the middle of the sternum. Later a small sore appeared in that situation, and on probing it I felt a rough substance. Enlarging it I found about two inches from the surface a needle which was considerably oxidized and very blunt. The canal had the appearance of an old sinus, and was about four inches long.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 24, 1883, to March 3, 1883.

BURTON, HENRY G., Captain and Assistant Surgeon. The leave of absence granted October 2, 1882, is extended two months. S. O. 49, par. 2, A. G. O., February 28, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 3, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
February 24, 1883.....	0	11	86	4	81	44	1	0
March 3, 1883	0	8	69	6	100	49	3	0

SOME DELUSIONS REGARDING THE DIGESTION OF OYSTERS.—Some experiments with oysters by Dr. Chas. L. Dana (*Med. and Surg. Reporter*) dispel certain delusions concerning that bivalve. He finds that it does not possess the power of digesting itself, as has been asserted by some; that raw oysters are not always more digestible than cooked ones, but that when roasted they are digested very nearly as rapidly as when eaten raw; that fermented liquors do not have any special power in dissolving them (as claimed by Professor Haughton) or in assisting their digestion.

THE ANTISEPSIS OF TUBERCULOSIS.—M. Vulpian, as the result of numerous experiments with tuberculous virus, recommends sulphurous acid as the most powerful destroyer of its specific properties.

THE FRENCH MEDICAL POLITICAL LEADER.—Dr. Georges Clémenceau, the present leader of the Left in the French Assembly, is the descendant of a line of physicians. He began his medical studies in Nantes, and subsequently studied in Paris under Robin, now a Senator. He was admitted to the degree of Doctor of Medicine in 1865, on the strength of a remarkable thesis on the generation of anatomic elements, a thesis in which he expounded and formulated the theories which Dr. Robin had scattered confusedly in a score of diffuse volumes. M. Clémenceau's thesis remains up to this day one of the best expositions of the theories in question. The theory itself, however, is no longer entertained by physiologists. M. Clémenceau practised medicine until 1875. He then definitely abandoned his profession for politics, being elected Radical Deputy for the arrondissement of Montmartre. He represents extreme republican and materialistic opinions.

SMALL DOSES FREQUENTLY REPEATED.—In urticaria Dr. A. A. Smith recommends (*New York Medical Journal*) two grains salicylate of soda every hour or half-hour. In spasmodic croup, one one-hundredth of a grain of atropia in a goblet of water, a teaspoonful every hour or half-hour. In the nervous disturbances and excitements of children, the bromides in one or two-grain doses every ten or fifteen minutes. Teaspoonful doses of a solution of tartar emetic, one grain in a quart of water, given frequently, will relieve the wheezing and cough of a slight

bronchitis in children. In orchitis and epididymitis, and also in dysmenorrhœa, two-minim doses of tincture of pulsatilla every hour are most efficient. Hemorrhages from the uterus and hæmorrhoids will generally be stopped by two minims of the tincture of hamamelis every half-hour.

MORE ABOUT CEPHALHEMATOMATA.—Dr. P. L. Myers, of Fostoria, O., writes: "Dr. H. M. Battershall's case of 'subpericranial cephalhæmatoma,' reported in THE RECORD of January 27th, appears to have been peculiarly formidable. The doctor's action in early removing the '—oma' is certainly commendable; as death, in time, would have undoubtedly resulted—from the first effort of the child to utter the name of its difficulty. Last May I attended a multipara in confinement. Labor easy. The following day the nurse noticed a swelling over the sagittal suture. It was one and one-half inch in diameter, soft, fluctuating, and irreducible. As it caused no pain or uneasiness (to the child) I let it alone. After two days it was found considerably enlarged. I aspirated with a hypodermic needle. The dark blood not escaping freely, I made a small opening with a bistoury. After two more days there remained no trace of the tumor. The parents seemed sufficiently awed when I explained it to them as a 'blood-blister.'"

[Our correspondent could hardly claim his case to be a "subpericranial" hæmatoma, since these are very rare, and occur over bones, not sutures. Dr. Battershall also cannot be said to have proved his case positively to be subpericranial, although it seemed probable that it was such, and hence its interest.—ED.]

Dr. G. Frank Lydston, of Chicago, Ill., also sends us the history of a case of ordinary cephalhæmatoma, resembling that of Dr. Myers'.

A CASE OF UREMIC COMA HASTENED BY A DOSE OF MORPHINE.—Dr. E. T. Hubbard, of Madison, N. H., sends the history of a patient, a farmer, aged sixty, who had been suffering for fifteen years with attacks of renal colic. In the last six months cedema of the legs had appeared, with scanty urine. Dr. Hubbard was called to see him while suffering from the colic, and he gave half a grain of morphine in the course of an hour. He was relieved, but after a time fell into a coma, from which he was but partially aroused by most energetic treatment during the next three days. At the end of that time he died. Our correspondent thinks that "probably the uræmic condition existed in the system, and all it wanted was the morphia to fire the train."

WARTS may be removed by the continuous application of mercurial ointment containing five per cent. of arsenic. Prof Unna recommends this, or a plaster containing in each 0.2 square meter (eight square inches) ten grammes (154 grains) of arsenic and half that quantity of mercury.

THE LAST NIGHT OF THE HOUSE.—A Washington correspondent writes that during the last night of the House, some of the members began to relieve themselves from the strain of their assiduous statesmanship by throwing paper wads at drowsy members. One big wad struck the face of Dr. McLean, of Missouri, a manufacturer of patent medicines, who writes his name, "Hon. Dr. McLean, M.C." The member in question called a page and sent his assailant a bottle of his last patent mixture.

ANTE-PARTUM HOUR-GLASS CONTRACTION OF THE UTERUS.—Dr. H. W. Dorman, of Ashtabula, Ohio, relates the history of a case which seems to have been one of ante-partum hour-glass contraction. The patient was a young and healthy Swede in her third labor. The head was in the first position, and the pains strong, but although the neck dilated well, the child made no progress. Dr. Dorman then passed his hand into the uterus and felt a constriction near the child's neck which nearly baffled all his strength to dilate. He succeeded,

however. The membranes were then ruptured and the progress of the child thereby favored. Delivery was at last successfully accomplished. The whole duration of the labor was eighteen hours. A constriction was found around the placenta.

FURTHER FACTS FROM THE TENTH CENSUS.—*The Coffin Industry of the United States* employs 3,762 hands and manufactures goods to the value of eight millions annually.

The Number of Midwives in the United States is 2,118. The number of nurses is 13,483, of whom 1,189 are male and 12,294 are female.

Surgical Instruments are manufactured in the United States yearly to the value of nearly a million of dollars. The number of establishments is seventy-one.

The Number of Veterinary Surgeons in the Country, according to the last Census, is 2,130. Of these 1,457 are natives of the United States, 104 of Ireland, 156 of Germany, 252 of Great Britain, and 171 of other countries. According to a register prepared with much care by the *Journal of Comparative Medicine*, only about one-half of these have degrees.

ANECDOTES OF THE LATE SIR THOMAS WATSON.—The following are a few of the many anecdotes told by the late Sir Thomas Watson (*British Medical Journal*):

When attending Lawrence, the great surgeon, when he had hemiplegia with aphasia, it was thought desirable to give to the patient some sedative. Lawrence, knowing this, and wishing to indicate what remedy he desired, was unable to find the word he wanted, and became greatly agitated in consequence. Sir Thomas Watson got pen, paper, and ink, and asked him to write the word. This he could not do, but, taking the pen full of ink, made a large splash on the paper, and offering it to those at his side. Sir Thomas Watson at once perceived the drift of this, and saw that his patient wished for the "black drop," a discovery which greatly delighted and satisfied Lawrence. Once, when dining at a large dinner party where Lawrence and Brodie were, the former remarked that Abernethy was the only genius in surgery he had ever seen.

Sir Thomas, in relating some of his professional experiences, used to mention the extensive amount of venesection which he had witnessed, relating an instance in which a man in Edinburgh was bled to seventy ounces by a clinical clerk, and with benefit, having been told to let blood until a sensible alteration was produced on the pulse.

He remembered the following as having happened: When at the Middlesex Hospital, he once saw a chimney-pot fall to the ground, and out of it jumped a sweep-boy, who immediately ran away, unhurt, for fear of being beaten.

He used to relate that, after a letter of his in the *Times* on the cattle-plague, some one wrote to him from Norwich to ask him to come down and vaccinate his cattle. Watson replied "he did not know how."

Once, when dining in company with Mr. Richmond, and the conversation turning upon sporting, the latter said, "Well, he had never put a gun to his shoulder, and supposed that by not shooting he *missed a good deal*." Watson replied that, "if he did shoot he probably would *miss a good deal more*."

He told the story of 'some one at a medical dinner party asking another, "Well, what's the news?" "Oh," said his friend next to him, "Dr. Jones has refused a fee, Dr. Smith has taken one, and Dr. Smithson has had one offered to him."

SOME RARE FORMS OF DISLOCATION OF THE ARM.—Dr. Leopold Meyer, of Copenhagen, Denmark, reports three unusual cases of dislocation of the arm. The first two were cases of *luxatio humeri erecta*, so termed by Middeldorpf in 1859. The patients presented all the characteristic signs of subglenoidal dislocation, but with exaggerated abduction, the arm being elevated nearly to

a vertical position and the hand resting on the head. The third case was that of a woman who had fallen backward while carrying a pail of water in each hand. She had a subcoracoid dislocation on both sides. In all these cases reduction was easily effected.—*Nordiskt Medicinskt Arkiv*, vol. xiv., No. 23, 1882.

HOT WATER AS A TIPPLe.—An English physician writes, in *The World of Science*, some very interesting things regarding what to drink. "The habit of drinking strong tea, or black coffee, directly after dinner, is especially bad, and certainly interferes with digestion. At breakfast time a healthy man has all his sleep in him, and surely it is then unscientific for him to inflict upon his system strong tea or coffee. At 'tea-time' tea or coffee may well be indulged in moderately; the bulk of the day's work is done; the body not only wants rinsing out, but fatigue is felt which may well be counteracted by the use of a mild stimulant, such as tea; and bedtime is not yet so near that sleep is thereby interfered with. Most nations that drink coffee largely get a sallow skin; and I am inclined to think that the carbonaceous matter of the roasted coffee, when so largely and frequently taken, may perhaps have something to do with this. For hard-working people, who are not corpulent, I should suggest the thick flake-cocoa as the healthiest and most nutritious breakfast beverage. For those who do not want fattening drinks, and who often cannot digest cocoa, I should say drink hot water at breakfast. Those who dine late, and make their dinner their main meal, need a diluent drink an hour or two afterward, and if they drink tea it keeps them awake or makes them irritable and nervous. I find for myself that dining solidly, as I am obliged to do when I have done my work (7.30 P.M.), and often needing to work from 9 to 11, a tumbler of hot water brought into my study or laboratory is the best and wholesomest drink, and, after a few evenings, it will be as much relished as the usual draught of tea. The hot water assists to complete the digestion of residual food, it acts upon the kidneys, and rinses out the effete matters, and thus will be found to wake one up sufficiently, and neither to injure the stomach nor to keep the brain awake after bedtime. In cold weather warm water is by far the best drink at dinner time, and in hot weather a draught of warm water is far wholesomer and more cooling than cold or iced water."

MOST ARTFUL.—The *Western Medical Reporter* says: "For patients who have to use iodoform for certain purposes it is advised to spread some of the ointment on muslin and bandage a finger with it. Thus the purpose for which the agent is used can be concealed." Such a pleasing and (at meal times) appetizing arrangement may deceive the children of Light who populate the great West; but we fear that the children of Darkness, as generally met with nearer the Atlantic coast, would look with scorn upon so transparent a subterfuge.

DR. OLIVER WENDELL HOLMES, on retiring from his professorship at Harvard, received the following pleasant greeting from London *Punch*:

"Your health, dear 'Autocrat!' All England owns Your instrument's the lyre, and *not* 'the bones.'
Yet hear our wishes—trust us they're not cold ones!—
That though you give up bones, you may make old ones."

IPECAC DURING LABOR.—Dr. N. P. Reeves, of Grand Cane, La., referring to Dr. Pitkin's article in THE RECORD on the above subject, reports two successful cases (*New Orleans Medical and Surgical Journal*) in his own practice. He says in conclusion: "I, like Dr. P., never thought that ipecac increased the muscular power of the uterus; indeed I have inclined to the opinion that it *lessened* it, to some extent; yet, by its relaxing powers and co-ordinating influences it lessens the danger and greatly facilitates the desired end."

SALICIN in half-drachm doses every two hours will relieve acute coryza.

SLEEP-DRUNKENNESS.—A gentleman living in this city recently suffered from a very severe attack of nightmare. He imagined himself assaulted by highwaymen, and in his struggles he severely injured his affectionate and unconscious spouse. A surgeon had to be summoned, and the case was thought of sufficient interest to be put in the hands of reporters. These enterprising gentlemen consulted a number of medical luminaries from whom much valuable information was obtained.

It appeared that the case in question was not a simple one of nightmare from a late supper or an extra piece of Christmas pudding. It belonged to a well-understood and defined derangement of sleep known as *somnolentia* or sleep-drunkenness. It is a condition, said an eminent neurologist, in which some of the mental faculties and senses are fully awakened, others but partially so, while still others remain in the quietness of sleep. It is generally brought about by the sudden awakening of a person from a sound sleep. In children such derangements occur quite frequently; while a few persons are subject to them all their lives. Serious injuries have been inflicted by these sleep-drunken individuals, and works of medical jurisprudence discuss the questions of responsibility thus raised.

A COMPLICATED MONSTROSITY.—Dr. S. C. Franks, of Bentonsport, Iowa, sends us an account of a monstrosity delivered by him from a healthy primipara at full term. The monster, which was born dead, presented the following peculiarities: The brain protruded from posterior fontanelle with placenta adherent. Left eye much smaller than right. Double hare-lip. An opening reaching from the third rib to os pubis from which protruded heart, liver, stomach, and intestines. The forearms were flexed at right angles with arm and ankylosed. Right knee flexed and ankylosed so that the heel rested against the nates, and lastly double talipes varus. Both parents were healthy and of the laboring class. Our correspondent gives no details of prenatal history.

UTERO-OVARIAN DISEASE IN INSANE WOMEN.—Dr. Margaret A. Cleaves, Physician to the Female Department of the State Lunatic Asylum, Harrisburg, Pa., writes in her annual report: "Briefly formulated, my conclusions, then, are as follows: that a large proportion of women in insane hospitals have some form or another of utero-ovarian disease; that many of those under treatment make marked mental and physical improvement coincidently with the improved local condition, that in a majority of cases, however, this improvement, owing doubtless to the long standing of the combined physical and mental disorder, only reaches a certain point, beyond which it seems impossible to make further gain."

CALX SULPHURATA.—Dr. H. G. Piffard (*Journal of Cutaneous and Venereal Diseases*) says that calx sulphurata (commonly misnamed sulphide of calcium) is a mixture of the sulphide and sulphate of calcium, but contains not less than thirty-six per cent. (U. S. Pharm.) of the former substance. He adds: "My own experiences, extending over a series of years, lead me to the inference that the drug is an aplastic or resolvent of great energy; that its tendency, when given in sufficient doses, is to break down and dissolve, rather than build up and restore. This theory of its action is in perfect harmony with the observed effects of its administration; and if it be the correct explanation, it will lead us to a multitude of useful applications of the drug. In other words, it appears to me probable that calx sulphurata will be found capable of fulfilling the rôle that was assigned to mercury thirty and forty years ago, that of a general solvent in inflammatory exudations, chronic infiltrations, and possibly also in some forms of neoplasm."

TRITURATIONS.—Of late years the adoption of finely pulverized combinations of sugar of milk with medicinal substances has so largely increased that it has become practically impossible to supply the demand, without making use of some other than manual power. The in-

troduction of "triturations" and "abstracts" into the new Pharmacopœia is very likely to increase still more the demand for this class of preparations. Triturating machines that go by steam have, therefore, been introduced by some pharmacists.

THE "HAMMOND PRIZE" OF THE AMERICAN NEUROLOGICAL ASSOCIATION.—The American Neurological Association offers a prize of five hundred dollars, to be known as the "William A. Hammond Prize," and to be awarded at the meeting in June, 1884, to the author of the best essay on the "Functions of the Thalamus in Man." The conditions under which this prize is to be awarded are as follows:—The prize is open to competitors of all nationalities. The essays are to be based upon original observations and experiments on man and the lower animals. The competing essays must be written in the English, French, or German languages: if in the last, the manuscript is to be in the Italian handwriting. Essays are to be sent (postage prepaid) to the Secretary of the Prize Committee, Dr. E. C. Seguin, 41 West Twentieth Street, New York City, on or before February 1, 1884; each essay to be marked by a distinctive device or motto, and accompanied by a sealed envelope bearing the same device or motto, and containing the author's visiting card. The successful essay will be the property of the Association, which will assume the care of its publication. Any intimation tending to reveal the authorship of any of the essays submitted, whether directly or indirectly conveyed to the Committee or to any member thereof, shall exclude the essay from competition. The award of the prize will be announced by the undersigned Committee; and will be publicly declared by the President of the Association at the meeting in June, 1884. The amount of the prize will be given to the successful competitor in gold coin of the United States, or, if he prefer it, in the shape of a gold medal bearing a suitable device and inscription. Signed, F. T. Miles, M.D., Baltimore; J. S. Jewell, M.D., Chicago; E. C. Seguin, M.D., New York.

IODIDE OF LITHIUM.—Iodide of lithium is said, by a writer in the *British Medical Journal*, to be the most useful of the lithium salts in the treatment of gout. Not only is it serviceable in well-developed cases, but also in the varieties of eczema and dyspepsia which are of gouty origin.

DR. RICHARD MEADE, who became so famous in the seventeenth century, made himself remarkable among other things as the doctor who fought a duel. It was with Woodward, who had not only attacked him in his writings but had insulted him in public. Matters came to a climax one day when they were leaving Gresham College, and Meade's patience gave way. He drew and called upon Woodward to defend himself. It is related that Meade succeeded in disarming Woodward and telling him to beg for his life. "Never, till I am your patient," was the reply.

A FAMOUS PRESCRIPTION FOR EPILEPSY in the eighteenth century was made from the *corvus epilepticus* or anti-epileptic crow. It is given by Ashtun in "Social Life in the Time of Queen Anne," as follows:

R. Of raven's flesh in powder..... ʒij.
Viper powder..... ʒj.
Native cinnamon..... ʒj.

Mix and make a subtil powder for two doses, to be given at night on going to bed.

LONGEVITY OF MEDICAL MEN.—A London paper notes that during the year 1882 twenty English medical men died at an age varying between seventy-eight and ninety-six.

DR. W. W. D. PARSONS, of Fultonville, N. Y., writes to say that he is not the gentleman to whom reference was made in the paragraph published in the issue of February 24th, on page 213.

Original Lectures.

ON THE RELATIONS OF MICRO-ORGANISMS TO DIS- EASE.

THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE
ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSI-
CIANS AND SURGEONS, NEW YORK.

BY WILLIAM T. BELFIELD, M.D.,

LECTURER ON PATHOLOGY, AND ON GENITO-URINARY DISEASES (POST-GRADUATE
COURSE), RUSH MEDICAL COLLEGE, CHICAGO.

LECTURE III.—(CONTINUED).

THE numerous examinations of tuberculous tissues revealed occasionally bacteria, which the discoverers were but too willing to consider the cause of the disease; Klebs, Schüller, and Aufrecht severally announced but failed to demonstrate that the infective agent had been found and that it was a bacterium. The lack of evidence in support of their statements, as well as the reserve with which such assertions in general were received, combined to reduce to a minimum the attention bestowed upon them. Such was the state of affairs when Koch read before the Physiological Society of Berlin a paper whose contents were in forty-eight hours telegraphed over the world. Koch's statements are so familiar to all, that detailed repetition would be superfluous; they may be summarized in the assertion that the active agent in the induction and propagation of tuberculosis is a distinct species of bacterium, a bacillus; that tuberculosis does not occur without the presence of this organism; that conversely all those anatomical changes and only those should be called tuberculosis whose point of departure from the normal condition is the presence and vital activity of this bacillus; hence, general and local miliary tuberculosis, cheesy pneumonia and bronchitis certainly, fungus-joint granulations, scrofulous inflammation of lymph-glands probably, and the pearl disease of cattle, are etiologically identical. The point of chief interest is of course the assertion that tuberculosis and cheesy pneumonia, pulmonary consumption, are caused by the bacillus. The evidence in its favor is first the experimental work of Koch himself, and then the unanimous confirmation of those of his statements which have been already tested.

His experience with and knowledge of bacteria found in the animal body is by general consent admitted to be excelled by that of no other observer; his caution and conservatism and the accuracy of his methods are such that, although he has for eight years been constantly working and frequently writing on this subject, he has never as yet been detected in a single error of observation; his facilities and opportunities in the Imperial German Health Bureau are unexcelled. The confidence and good will of government and people alike—for Koch's is an official position, you know—would be destroyed by any ill-executed observations, or by any injudicious and untenable assertions in this, the most important and widely circulated of all his works. That Koch appreciated the situation is shown by his course in the matter: having discovered the bacilli in tuberculous tissue, he did not send an announcement to the Academy of Sciences nor blazon it through the medical press; he

kept it to himself, satisfied himself that this was a constant, not an occasional or accidental association; that the same bacteria were present in the spontaneous tuberculosis of animals—the hog, chicken, ape, guinea-pig, and rabbit; then he devised, by experimentation, a proper medium, *solid* of course, for cultivating the organisms outside of the animal body under constant microscopic supervision, comparing them with fresh bacilli from tuberculous tissues; satisfied himself again by personal experiment of the inoculability of tuberculosis; found that while vaccination of the rabbit or guinea-pig with fresh tuberculous matter induced the disease, inoculation with such material after lying in alcohol for a month or dry for two months, was impotent to cause the disease, and *contained no living bacilli*; found that the bacteria were often, *not always*, present in the sputum of tuberculous patients, but never, so far as examined, in that of others. Having thus made a preliminary investigation, Koch proceeded to the experimentum crucis with bacilli which had grown from the tuberculous tissue under his eyes; which were therefore proved to be the progeny of the original ones, not by the theory of probabilities, not simply by their identical size, shape, and chemical reaction, but by the fact that he had seen them proceed from the first as continuities of structure; which were seen under the microscope to be quite free from any foreign solid matter, bacterial or other; which were proven to be equally free from any foreign matter in solution because growing in successive cultures upon solid soil; which had been carried from the first to the eighth generation; which had been thus isolated from the original animal tissues three, four, five, even six months. With these isolated descendants of the bacilli found in tuberculous tissues, Koch inoculated numerous animals—using over two hundred altogether—not only the susceptible rabbits and guinea-pigs, but also cats, a dog, white rats which had resisted inoculation by injection and by feeding with tuberculous materials, and field mice. Inoculation was made in the skin, the abdomen, the eye. In every case tuberculosis and tubercle bacilli were found in the infected animal.

Having spent *two years* in the completion of this work, amid all the facilities of the imperial laboratory; having meanwhile permitted himself no public intimation of the same, Koch quietly announced his results at a regular meeting of a medical society, with as little ostentation as if he had merely appropriated a chapter from Ziemssen. One whose knowledge of bacteria and of disease is not such as to permit a technical appreciation of Koch's work, cannot help seeing in the unobtrusive, systematic, and undeviating work of two years, and in the modest announcement of the result, that Koch's work is not to be classed with that of Klebs, or Letzerich, or even Pasteur. I would call your attention to the fact that Koch's assertion embodies not a theory, but simply an ocular demonstration. If a man is seen to plunge a knife into the heart of another the killing is a fact, not a theory; if Koch saw tuberculosis invariably follow the introduction of isolated bacilli, the relation of cause and effect is a *fact*, not a theory. There is only one possible escape (I use this word intentionally out of regard for the prejudices of many friends) from the conclusion that the bacillus causes tuberculosis; and this forlorn hope is the possibility that Koch did not see what he says he saw—that he made some vital error of observation. This is of course possible, though if true it will be the first error

that the most searching scrutiny could ever detect in his observations; that it is improbable is evident.

If we accept Koch's observations as accurate, there is only one conclusion—that these bacilli cause tuberculosis. For here the conclusion and the observation are identical; this is not a deduction, but a demonstration.

And how shall it be decided that this work is or is not free from errors of observation? Certainly not by saying that it cannot be so; not by exhuming Niemeyer's buried argument that tuberculosis is not infectious; but simply and solely through the repetition, by competent observers, of the same work. Until such repetition shall detect serious errors of observation, Koch's work stands unchallenged—more accurate and complete investigation can scarcely be conceived. On the other hand, until such repetition shall confirm Koch's observations, we may justly decline to accept them unreservedly, on the ground that he *may* have made his first error in this his greatest effort.

While, however, Koch's main assertion, that the bacilli cause tuberculosis, can be competently criticised only by the few men who like himself have the time, facilities, and skill necessary to conduct such tedious and delicate experimental observations, yet some of the preliminary assertions fall within the range of a larger circle of critics, and have been already subjected to extensive investigation. The results are as yet unanimous in confirming the original assertions of Koch that the bacilli are to be found in the sputum from most though not all cases of pulmonary tuberculosis, and, what is quite as significant, have never been found in any other sputum.

Ehrlich, Balmer and Fräntzel, Guttman, d'Espine, Lichtheim, Fränkel, Ziehl, Heron, Gibbes, Green, West, Yeo, Whipple, Councilman, have already recorded their unanimous experience that while the bacilli are found in the sputum in at least a large majority of cases of pulmonary consumption and tuberculosis, they are not found in any other disease. Balmer and Fräntzel found them always in their one hundred and twenty cases, but never in bronchitis. Ziehl recognized them in nearly all of seventy-three cases, but never in thirty-four other cases, including acute and chronic bronchitis, acute fibrous pneumonia, gangrene of the lungs—indeed all pulmonary diseases that he had opportunity to examine. It should be remembered that Koch failed to find them in the sputum from a certain number of cases. In the tubercles of tuberculosis and in the cheesy matter of consumptive lungs the bacilli are usually present—not always, as Koch himself discovered. Whether their absence from certain tubercles is to be explained, as Koch suggests, by the death of the organisms and their consequent failure to absorb aniline colors, or whether some of these tubercles arise from other causes than the presence of these, may be perhaps an open question. Gibbes' experience—that the bacilli are present in only one reticular nodule out of ten, but in nearly all non-reticular tubercles—might, perhaps, support another explanation. Certainly the absence of the organisms from tuberculous tissue is the exception. On the other hand, the bacillus is never found in the body except in tuberculosis; the only suggestion to the contrary is the recent assertion of Koranyi that he found similar organisms in a case which he believed to be pulmonary syphilis, and not consumption.

Such, then, is the state of the case to-day: Koch's assertion of the association of the bacillus with tuberculosis—its presence in every case of the disease, its absence in all other morbid conditions—confirmed by all who have investigated; his assertion of the causal relation of the parasite to the process—based upon a demonstration unexcelled in the history of experimental science for accuracy, clearness, and completeness—as yet unchallenged.

The subject might be properly left here; but I deem it advisable to consider briefly two recent publications, not because they demand consideration by one familiar with

the facts, but because they may have influenced some who derive their information chiefly from American literature.

A few months ago there was heard a scream of exultation from a Western journal, soon echoed on many sides. The attention of press and public alike was attracted to the jubilant cry that Koch, bacillus, and bacteria were to be annihilated; that the "bacillary craze" of German pathologists; the absurd fancy that a small organism could harm a large one; the comical idea that an experienced mycologist should know more about bacteria than a practising physician; the barbarous doctrine that our loved ones could be subject to infectious diseases; all these and similar absurdities which pseudo-scientists had vainly attempted to foist upon our superior intelligence would be forever buried. The American eagle, that implacable devourer of microscopic poultry, would consent to leave for a brief time its favorite swamp at the "delta of the Mississippi," and by a single act of deglutition would teach our terrified friends, "the micro-pathologists," to "take their eyes from their mounted specimens," and engage in less disreputable pursuits. So ran the widely advertised programme. After weeks of joyous anticipation the appointed day arrived; a distinguished microscopist, whose skill in mycology had been amply indicated by his failure to detect the bacilli always present in leprosy tissue, appeared in the arena armed with the startling discovery that if caustic potash solution be added to fattily degenerated tissue, crystals of fatty acid appear! The announcement was greeted by the audience of assembled experts with rounds of applause—"Sic transit bacteria," etc. Again has free America repelled the assaults of effete Europe.

I had intended to offer some remarks upon this matter, suggested by the evident fact that Koch's bacillus and Schmidt's crystal were different objects; but criticism is no longer necessary. Dr. Whittaker has stated the case very clearly; Dr. Hunt has shown that the crystal polarizes light, while the bacillus does not; and I have received from Dr. Schmidt a letter which disarms criticism.

After reading his article, I sent him a slide of sputum containing the bacilli; in his reply he says, "From what I understand now the minute crystalline rods which I discovered are not identical with Koch's bacilli;" and later, "the failure with which I met in my attempts of staining the bacillus tuberculosis, appears to have been due to the worthless aniline oil which I have used." I interpret these sentences as a candid admission that the crystal and the bacillus are not identical, and shall therefore refrain from further remark. Such admission, by proving sincerity of purpose, transfers to his friends of the antibacterial "camp" the obloquy and chagrin consequent upon the blare of trumpets with which this publication was heralded; the mouse may be *per se* a highly respectable and by no means ridiculous animal, though its advent as the result of herculean efforts at parturition is said to be very absurd. This entire matter can hardly fail to teach far more effectually than lectures, that trustworthy investigations on this subject demand not only skill and experience in pathology, which Dr. Schmidt undoubtedly possesses, but also acquaintance with the special methods involved.

A paper called "The Bacillus Tuberculosis," by Dr. H. F. Formad, of Philadelphia (*Philadelphia Medical Times*, November 18, 1882, reprint), opens with the announcement that the author "will bring forward some points from researches of my own, which will check the acceptance of the doctrine of the parasitic origin of tuberculosis;" "my anatomical researches will also surely throw grave doubts upon the correctness of Koch's views on the etiology of tuberculosis" (p. 2). The author fails to discriminate between the bacillus and the infectiousness of tuberculosis, which is in this article, however, a matter of little consequence, except as an index to the general accuracy of the publication.

The original researches which are to destroy the

"parasitic theory" consist, curiously enough, in the time-honored demonstration that tuberculosis often occurs in certain animals (notably the rabbit and guinea-pig) after simple wounds, the irritation caused by glass, etc.; especially if the animals be carefully confined in a pathological laboratory where many others have died of this disease. As Dr. Formad has seen "more than one hundred rabbits, out of five or six hundred operated upon," die of tuberculosis, we may infer that in his laboratory there was no lack of tuberculous material for infection.

There is, however, one original feature in this work as reported by Dr. Formad. Actuated doubtless by a commendable high-tariff spirit of protection for American industry, while quoting copiously his own students, he resolutely ignores the work of Burdon-Sanderson, Cohnheim, and a dozen others who have, during the last fifteen years, performed the original experiments of which his own are repetitions; and neglects to state that Cohnheim and Fränkel found that while these experiments succeeded admirably in the Berlin laboratory where many animals had long been confined, no tuberculosis occurred in a subsequent repetition in a private dwelling. On the same principle, perhaps, he neglects to state that for such reasons as these, such experiments as his own were years ago abandoned to amateurs, while the battle for infectiousness was fought and won in the eye, the lung, and the intestine, as above stated. Perhaps Dr. Formad will kindly explain how he came to deny the infectiousness of tuberculosis merely on the strength of these long since abandoned experiments, without a solitary experiment, or even reference to an experiment, on the eye, etc.

Because in his experiments no tubercular matter was "intentionally or knowingly" introduced, he maintains that nothing could have entered; that the disease is therefore not specific nor infectious. Surgeons, then, intentionally and consciously inoculate their patients with pyæmic, diphtheritic, and erysipelatous material. It will not help Dr. Formad to deny, as a New York microscopist in the same dilemma has curiously done (*MEDICAL RECORD*, March 3, p. 247), that pyæmia is infectious. For in the *National Board of Health Bulletin*, Sup. No. 17, Formad asserts and attempts to prove the infectiousness of diphtheria, and says (p. 18): "A case may begin as one of sthenic pseudo-membranous croup, and end as one of adynamic diphtheria with blood-poisoning; and in cases of this character, not infrequently, *no exposure to contagion is discoverable*." ¹ Perhaps he will explain why the absence of intentional or conscious inoculation, even of discoverable exposure to contagion, is perfectly compatible with the infectiousness of diphtheria, and yet proves the non-infectiousness of tuberculosis. Formad says (p. 2): "I can positively prove that true tuberculosis may be produced without the bacilli in question." The only proof adduced for this important statement is the experiment with glass, etc., in which the disease occurs without any "conscious or intentional" introduction of the bacillus, and the *assumption* that the organisms were therefore absent; if, however, the parasites be nevertheless present in such cases, this assertion is evidently unwarranted. We are not informed on this point in the paper, although we may infer their presence from the following statement (p. 11): "Koch has discovered that tubercle-tissue is *always* infested by bacilli, and this is correct." ² To secure definite information, I addressed to Dr. Formad, some months ago, three several letters, enclosing stamps, requesting him to state, for incorporation in these lectures, whether he had examined these cases of tuberculosis following wounds, mechanical irritation, etc., to ascertain the presence or absence of the bacilli, and if so, with what result. To these letters I have received no reply. ³

As to the association of the bacilli with tuberculosis, Formad's limited observations seem to agree with Koch's statements. ¹

The one novelty—which I am charitably disposed to think explains the existence as well as the peculiar character of this paper—is a theory that the susceptibility to tuberculosis is inversely proportional to the width of lymph-spaces; whence (by a process of reasoning peculiar to the author) he makes the deduction that no etiological influence other than inflammation and narrow lymph-spaces is necessary to induce tuberculosis. It is useless to remind Dr. Formad of the induction of tuberculosis in the eye, lung, and intestine, since he ignores pathological work which does not emanate from himself or his pupils. But since by a singular coincidence the rabbit and guinea-pig—the animals exhibiting typical narrow lymph-spaces—are peculiarly susceptible, the dog and cat insusceptible to anthrax as well as to tuberculosis, I would suggest the possibility that the etiology of anthrax also may be found, not in a bacillus as the Europeans suppose, but in narrow lymph-spaces. ²

Dr. Formad promulgates the dogma (p. 3) "Scrofulous beings" (*i.e.*, those with narrow lymph-spaces) "can have no other than a tuberculous inflammation, although it may remain local and harmless." Are scrofulous beings, then, assured against syphilitic, erysipelatous, diphtheritic inflammations, or are these merely varieties of the tuberculous?

As yet the presence of the bacillus in sputum has possessed a confirmative rather than a diagnostic value, for in the cases in which it has been detected the diagnosis has been usually already assured by the physical signs. Whether or not the bacillus may be present in cases called chronic bronchitis, etc., where the symptoms and the family history beget a suspicion not yet supported by physical exploration, must be decided in the future. In this connection it may be proper to mention an instance which has fallen under my own observation. ³

A young gentleman of my acquaintance, in whose family history there is no record of consumption, but who had for months suffered from a persistent and annoying cough, requested me one day to examine a microscopic slide which he had prepared. The diagnosis was easy, tubercle bacilli in sputum. He then informed me that the sputum was his own. Physical exploration by one of our most experienced physicians revealed subsequently a circumscribed area of consolidation in the right lung.

Fränkel has always found the bacilli in laryngeal ulcers of tuberculous patients, but never in those of syphilitic or other individuals. Barrow found them in the urine from tuberculous kidneys in one case.

Not only the clinical, but also the anatomical investigation already reported, confirm Koch's statement that tuberculous tissue, whether occurring in miliary nodules or as cheesy masses, whether in lung, or liver, or spleen, peritoneum, or meninges, contain tubercle bacilli, and that no other tissue harbors them. Some, it is true, find a larger proportion than did Koch, of individual miliary tubercles, in which no bacilli can be detected; this is particularly true of Ziehl's examinations. Gibbes found the bacilli in reticular tubercle in only one nodule out of ten, in the non-reticular they were usually present. Koch was inclined to the belief that his failure to detect them was due to the fact that the organisms had lost their vitality, and hence their power of absorbing aniline dyes; and demonstrated instances in which a very imperfect staining of individual bacilli was visible. This explanation is certainly plausible, yet it is possible that tuberculosis, like individual tubercles, may be produced by any

hope that he may—he will perhaps state whether those letters were received; if so, whether he answered them; if he did not, why not.

¹ Paradox: "Tubercle tissue is always infested by bacilli," yet "true tuberculosis may be produced without" them.

² Dr. Formad will enlighten us, in subsequent "Pathological Studies," as to what he will permit us to call "true" tubercle, and announces that a student of his is incubating a cognate topic. Possibly we may yet learn what constitutes "true" pus; and how many spirits can stand on a needle-point.

³ I have recently learned from my friend Professor W. H. Welch, of New York, that two essentially similar cases are known to him.

¹ Italics mine.
² Koch, by the way, does not make this statement, which is, moreover, *not* correct, since Koch, Gibbes, Ziehl, Guttmann and others failed to detect the bacilli in a certain number of tubercles.

³ If Dr. Formad shall reply to these queries—and for many reasons I sincerely

one of several causes. The clinical picture exhibits many variations; the histological structure is not peculiar to tubercle. We have learned to distinguish trichinosis from typhoid fever; charbon symptomatique from charbon; actinomycosis from pyæmia and pulmonary consumption; indeed, Pflug observed in the lungs of a cow a miliary tuberculosis, and upon microscopic examination was surprised to find that the individual tubercles contained, not Koch's bacillus but the *actinomyces bovis*; this as yet solitary observation strengthens the suspicion that among the numerous agents whose presence excites the inflammation which results in tubercle formation, there may be other parasites than the bacillus of Koch; that there may be several diseases etiologically distinct, but anatomically so similar as to be included under the common name tuberculosis; the one characterized by the famous bacillus, others, possibly, by organisms yet to be discovered. In one instance, certainly, an analogy to this supposition has become a demonstrated fact. For thirty years it has been known that the disease called anthrax or charbon is characterized by the presence of a large bacillus; yet in some cases the site of inoculation was indicated not by a malignant pustule or carbuncle, but by a local necrosis with subcutaneous formation of gas. These cases were designated charbon symptomatique. Five years ago Bollinger discovered that the bacillus found in the so-called charbon symptomatique is another variety than the bacillus anthracis which characterizes the malignant pustule—distinguished by both morphological and physiological features. And now the two diseases are recognized as etiologically distinct, though anatomically and clinically almost identical. To-day we can say with Schottelius, that *one* infectious disease, one infectious *tuberculosis*, is characterized by the presence of Koch's bacillus, though there may be others, clinically and anatomically entitled to the same name, which future research may distinguish etiologically from *this* tuberculosis, just as charbon symptomatique has been distinguished from charbon. Indeed, some observers have already expressed the suspicion, based on their own investigations, that there is more than one bacillus tuberculosis.

The association of Koch's bacillus with tuberculous tissues, and its absence from other structures, is therefore demonstrated and acknowledged; and this fact, taken in connection with Koch's own demonstrations, constitutes an array of evidence which has induced numerous German, Austrian, and English pathologists to accept as a fact the vital activity of the bacillus as the starting-point of the disease. Among these is Billroth, whose acquiescence is notable not merely because of his eminence as pathologist and surgeon, but because his own elaborate researches upon bacteria, published in 1874 and still widely quoted, led him to the conclusion that these organisms appeared in human tissues as the result, and not as the cause of morbid processes. Billroth, like the German pathologists generally, is open to conviction.

Yet while we may have, probably have, found in this bacillus the object whose presence is followed by tuberculosis, we may not forget that the appearance of the disease implies not only the presence of this organism, but also the existence of animal tissues which permit the bacillus to exercise its vital functions. Many animals, even some rabbits, resist inoculation with the freshest tuberculous material. There is, in other words, a predisposition of the animal—an adaptation of his tissues favorable to the growth of this organism. The palm-tree cannot grow in Greenland; the oak does not flourish in the desert; the bacillus anthracis and the bacillus tuberculosis rarely grow in the body of a dog. And it may not be forgotten in the excitement over Koch's discovery, that there remains much to be done in determining the nature of this predisposition *of the animal soil to the growth of the tuberculous plant*. Thus far we are utterly in the dark. Dr. Formad thinks he discovers a ray of light issuing from certain narrow lymph-spaces.

If he will prove what he asserts, he will have made a valuable anatomical contribution; yet when we remember that rabbits and guinea-pigs are peculiarly susceptible not only to tuberculosis but also to anthrax, and that cats and dogs are as markedly insusceptible to the one disease as to the other, it becomes evident that there must be some factor in the common predisposition to both diseases alike, which is not visible in the field of the microscope.

Indeed, with all due honor to Koch, and admiration for the most brilliant of experimental researches, we must admit that the discovery of the bacillus has chiefly an anatomical value: it localizes in this organism the infectious principle which had long been known to exist; it enables us to distinguish—ante- and post-mortem—infectious tuberculosis from inflammation, tubercular or other, due to other causes; but it does not as yet explain the hereditary predisposition, nor why this infection occurs in one man and not in another exposed to the same influences.

A dozen questions should be considered in this connection—the etiological identity of scrofula, tuberculosis, and fungus joint granulations; the possible infection of the infant by the mother's breath and breast, by the application of a handkerchief to the child's nostrils, etc.

Yet time permits a reference, and that but brief, to one of the most important—the possibility of infection from tuberculous meat and milk. For the so-called pearl disease of cattle, while presenting certain histological differences—an excess of calcareous salts, ascribable to their vegetable food—from tuberculosis in man and other animals, would seem to have an identical etiology; since inoculation with minute pieces into the anterior chamber of the rabbit's eye gives precisely the same result—local and general tuberculosis—as is induced by the same quantity of human tuberculous tissue and by nothing else. The effects of introducing the two into the circulation are also identical. Indeed there now remain but few who are not satisfied of the etiological identity of the two processes, especially since Koch's bacillus is found to inhabit both tissues. Yet etiological identity does not prove the possibility of infecting the human subject with tuberculous meat and milk. For it is a principle that must be borne in mind—a principle which Pasteur, in his ideas of preventive vaccination seems to have forgotten, by the way—that a material which can infect a given animal when placed in the eye, may fail when introduced into the alimentary canal or even under the skin. Koch found, five years ago, that although a mouse is so susceptible to anthrax as to be a reliable reagent in testing the strength of anthrax material when introduced subcutaneously, yet all attempts to induce the disease in mice, as well as in rabbits, by feeding them with anthrax tissues or spores, were quite unsuccessful. Since anthrax bacilli grow best in a somewhat alkaline liquid, and not at all in one markedly acid, the explanation may lie in the general acidity of the gastric and intestinal secretions in the carnivora. But whatever the explanation the fact remains.

Many experiments have been made to determine the possibility of infecting animals by feeding them with tissues and milk from tuberculous cattle. Gerlach, Orth, Bollinger, Klebs, and Chauveau were almost invariably successful with herbivorous animals; but Colin, Günther, and Müller saw only negative results. Virchow, experimenting with pigs, achieved somewhat indecisive effects; and while not inclined to deny the identity of the two diseases, he thinks it not yet experimentally proven that tuberculosis can be induced in animals by feeding them with such meat and milk. While we may quite agree in this, yet when we consider the *probability* on anatomical and experimental evidence; when we remember the peculiar frequency of intestinal tuberculosis in infants, especially in those artificially nourished; when we think that thirty per cent. of certain herds of cattle are, according to Professor Law, demonstrably tuberculous; we may be inclined to dispense with further direct experimental evidence, and avoid such meat and milk.

Original Articles.

ROTHELN.

By D. N. KINSMAN, A.M., M.D.,

PROFESSOR OF PRACTICE OF MEDICINE, COLUMBUS MEDICAL COLLEGE, OHIO.

IN November, 1882, there was an outbreak of rotheln, or "German measles," in the Ohio Institution for the Deaf and Dumb. In this institution there are four hundred and fifty inmates. The sexes are about equally divided, and their ages range from six to eighteen years.

The pupils occupy four dormitories, two on each side of the main building. In each of these dormitories there are ninety beds, and one hundred sleepers. Two large halls are used in addition for the temporary accommodation of those for whom there is no place in the regular sleeping-rooms, when the institution is crowded as at present.

These conditions are obviously most favorable for the rapid spread of any infectious disease. During the winter of 1873 and 1874, so far as I know, rotheln made its first appearance in Central Ohio, when it was generally prevalent in this region.

It is also quite clear that it was not generally recognized as a new disease by the physicians, for during the last nine years I have frequently met persons, laboring under an attack of true measles, who asserted that about that time they had measles, and they were then suffering from a second attack. Occasionally, since 1874, I have met small groups of cases of rotheln.

The source of the infection which acted upon the inmates of the institution is unknown. I know of no cases being reported in the city before this outbreak.

The school had been in session since September 15th, much too long a period for the incubation of the disease in any pupil who could have been infected during the summer vacation. Therefore I am led to believe the disease was brought to the institution by some one of the many visitors, from all parts of the State, who are daily seen there. The first case was sent to the hospital on the afternoon of November 19th. The patient was a girl of seventeen. She had an irregularly outlined papular eruption, resembling the exanthem of measles, except that it was of lighter hue and in larger patches. Her eyes were red and watery and quite sensitive to light. She had some difficulty in swallowing. The throat was red and the uvula and half arches covered with red puncta. There was a hacking cough, and she complained of tightness in the chest. Pulse, 100; temperature, 98.6°. The eruption extended over the whole body and the extremities, being most marked on the back.

She said she had suffered from frontal headache and nausea the day before.

Believing the case to be one of measles I gave orders for her isolation, although I could not understand why a case of measles with so extensive an exanthem should show so little constitutional disturbance.

On the morning of the 20th the temperature was 98.6°; pulse, 90. The eruption had subsided on face and neck so as to be barely perceptible, while it was yet distinct on the portions of the body covered with clothing. The congestion of the eyes and cough had subsided, and the patient declared herself well.

The nature of the case was now evident, and the progress of the epidemic was from this time carefully observed. Cases reported at the hospital as follows:

	Girls.	Boys.
November 19th.....	1	0
" 20th.....	1	12
" 21st.....	1	4
" 22d.....	2	15
" 23d.....	5	7
" 24th.....	6	2
" 25th.....	2	2
" 26th.....	2	4
" 29th.....	1	0

From the last mentioned date there was a subsidence of the epidemic until December 9th, when it again appeared among the girls, and during the following five days 27 had the disease, and on the 15th 1 boy, making a total of 48 girls and 47 boys, or 95 cases in all among the mutes.

In addition, the assistant matron, a lady near fifty years; an officer, male, aged thirty; two children of the superintendent, and the daughter of the matron, were attacked, so that the institution furnished just one hundred cases.

All of the patients but five being mutes, it was difficult to secure as complete a history of the prodromes as I could desire, and still more, to increase this difficulty, many of the pupils who were attacked had entered the school at the beginning of the term, and hence had a limited knowledge of sign language. From the fact that many were seized in the schoolroom and the eruption was the first symptom noticed, I conclude in quite a proportion of cases there were no prodromes whatever. In some cases there was frontal headache, nausea, and vomiting, with vertigo. The assistant matron suffered much from headache and vertigo for twenty-four hours previous to the eruption.

In all cases there was suffusion of the eyes and in some abundant lachrymation, so that the tears ran over the cheeks. There was also a hacking cough, but by no means as severe as in measles. In one case I observed an extensive eruption of urticaria, with headache and nausea on one day. This was succeeded by an eruption of rotheln on the following day, with a complete subsidence of urticaria. In some other cases I observed a general congestion and swelling of the skin of the face and neck for several hours before the appearance of the typical eruption.

The duration of the prodromic stage was in most cases twenty-four hours. The exanthem appeared first on the face and neck, and in from two to six hours would develop over the whole body. Sometimes the eruption was slightly or not at all marked on the body and extremities, being limited to the face and neck. In other respects the eruption was subject to great variations. In one group of cases the exanthem was fine and there was a general blush of the integument, as in scarlatina; indeed, the resemblance to that disease was so close that in the absence of other characteristic cases of rotheln I should have been obliged to regard them cases of mild scarlet fever.

In another group of cases the exanthem consisted of discrete papules, from one-eighth to one-half an inch in diameter, closely resembling measles. Again, these papules would coalesce in large irregular patches an inch in diameter. This was especially the case upon the face of a boy who had acne, and in two girls who had pustules upon their faces. It was curious to observe the rapid changes the skin would undergo.

A boy came into the hospital while I was making my morning visit, his eyes were suffused and his face was covered with an erythematous blush. During the hour I was examining the other patients, the characteristic exanthem appeared, and the congestion had marked itself off into circumscribed territories around the papules. In the evening the papules alone were visible, the intervening skin having assumed its natural appearance. A boy, aged seventeen, on the first day of the eruption, had the ordinary papules; on the second day, each papule was surmounted by a vesicle. Some of these vesicles were globose and the size of a small shot; on the third day the drying of the vesicles was advanced, and on the fourth day complete. In this case the eruption was confined to the face and neck, and the exposed surfaces of the hands and wrists. There was no eruption on the palmar surfaces. The eruption was in all cases elevated and rough to the finger, and exfoliated in small branny scales. The patients all complained of the itching. On the decline of the eruption I observed in three cases a

puffy condition of the integument of the forehead, and in two cases oedema of the ankles. The urine was examined for casts and albumen with negative result.

The throat symptoms in all my cases were mild, in no case did I observe false membranes or ulcerations. There was a little swelling of the glands of the neck in a few cases, and in the cases where this occurred it was confined to the glands around the angle of the jaws. The mucous membrane of the soft palate was, with the uvula and tonsils, slightly swollen and dotted over with a multitude of prominent points like "goose-flesh" of the skin. In some of the throats I noticed dark mottling of the swollen membranes, which appeared to be due to minute extravasations of blood. These spots remained after the decline of the other symptoms, and were observed as late as the fourth day.

The tongue was usually covered with a thin white fur through which the papillae projected as red points. As a usual thing, the appetite was good after the second day, and was in no way impaired in the patients who had no nausea. The bowels were not disturbed. Headache was not severe in most cases, and the pain seemed to be confined to the frontal region. There were six cases in which the pain might be called severe, and was associated with vomiting. A careful examination of the cases in which the cough was worse failed to show any thing wrong with the bronchial tubes. There was no expectoration attending the cough. The temperature in one case reached 103° . Six cases registered 101.5° . I find ten recorded at 99.5° , while many reached 99° , but the largest number showed 98.6° . Chilly sensations were complained of frequently, and were especially noticed in all the patients who could speak. The pulse was in one case 110; most of the cases ranged from 85 to 90, while many never exceeded 80. I recognized no special odor among these patients such as is described by some writers. The duration of the eruption was usually three days. There was not a case in which I could recognize it as late as the sixth day, even on the protected surfaces. There were no critical discharges. I saw no decided complications. One boy who had the exanthem on the 24th, on the 27th had a decided chill followed by a croupous pneumonia. All of the patients who could speak said their muscles were sore and painful on movement for some days after the decline of the eruption. In four cases the fingers and wrists remained swollen and painful for several days.

One child was confined to bed for a week after the disappearance of the exanthem. In her case, in addition to the above-mentioned joint affection, there was general muscular soreness, which caused extreme suffering when she moved or when pressure was made upon the muscles. The soreness was the greatest over the extensor surfaces.

The disease is unquestionably contagious. The contagion is not so active as that of measles. The number of pupils attacked was twenty-one per cent. of the whole. Only three adults suffered from the disease out of about fifty who were employed in the institution, showing thus a diminution of susceptibility with increasing years. Of the nutes who suffered, twenty traced their deafness to scarlatina. Many of them had had measles, but as this was not recorded as the cause of their deafness in any of these patients I could not obtain definite information on this point. All these patients recovered, which would seem to justify an absolutely favorable prognosis.

Evidently from what has been written on this disease by British authors it is not always the mild affection which has been observed in America.

J. Lewis Smith says "it resembles varicella in general mildness of symptoms, in the absence of dangerous complications or sequelae, and in the uniformly favorable prognosis, while its symptoms and history show its close alliance with measles and scarlet fever."

Palmer says: "As the disease is so slight and devoid

of serious consequences no particular medicinal treatment is required."

Hartshorne, in "Reynolds' System of Medicine," indicates "an absence of any fatal cases."

Aitken, however, in his "Science and Practice of Medicine," gives an account of the lesions seen in fatal cases, and describes a much more active and intense form of morbid action than has ever been reported by any American author. He says the prognosis requires to be as guarded as in scarlatina, for, like scarlatina, rubella is often an extremely rapid and fatal disorder." Indeed, the account he has given, as to the duration and gravity of the disease, would lead one to think he had in mind some anomalous forms of measles and scarlatina, or a true hybrid instead of rotheln, as we have observed it.

Furthermore, by comparing the accounts given by Smith and Hartshorne with my observations, variations in local epidemics can be observed.

CYSTO-ABDOMINALRAPHY.

By ALEX. W. STEIN, M.D.,

SURGEON TO CHARITY HOSPITAL, NEW YORK.

SURGEONS are not in accord regarding the best method of dealing with a supra-pubic incision of the bladder. With some the open method is invariably adopted, others as uniformly suture the vesical wound, and drop the viscus into the pelvic cavity to take care of itself. While both methods have shown good results, they are far from being as satisfactory as could be desired. This will probably be admitted by the most ardent advocate of either procedure. The choice of a third and, as it would seem, a very safe operation, comes to us in the suggestion to bring the bladder-wound in apposition and in union with the abdominal wound. This proposition dates back as far as 1716, Joh. Jacob Hoyt ("Unterricht von den tödtlichen wunden des ganzen menschlichen Leibes"), but so far as I know has never been practically carried out until recently by Dr. T. G. Thomas, of this city, who, in the course of a laparotomy, found it necessary to open the bladder in order to determine the upper limit of the viscus which was adherent to the tumor. After the removal of the cyst, the lips of the vesical incision were drawn up and clamped between those of the abdominal wound by means of silver sutures. A Sims sigmoid catheter was kept in the bladder. The sutures were removed on the tenth day, and at the end of three months the patient went home entirely well. As a single instance of success can never establish the safety or feasibility of an operation for general adoption, I sought further evidence in the following experiments, the results of which, I think, tend strongly to confirm our confidence in the practicability of what may be called "cysto-abdominalraphy." The first three experiments were made last winter at the American Veterinary College, the latter five by my former assistant, Dr. R. H. Harrison, of Lowell, Mass., to whom, also, I am indebted for the notes:

EXPERIMENT I.—Brown dog, partly setter; weight about 60 pounds; three years old. Etherized; supra-pubic incision of abdomen. Bladder opened on the end of a catheter, introduced through a previously made perineal incision to the extent of an inch, and the vesical lips brought together with the abdominal wound by means of silk sutures. Lister's dressing; catheter tied in the bladder through perineal incision. Next day, temperature, 104° F.; pulse, 120; respiration, 18. No appetite; considerable depression. Catheter removed thirty-six hours after operation. On the second day, temperature, 102° F.; pulse, 110; respiration, 18; drinks a little milk. From this time dog rapidly improved; sutures remained five days, but urine escaped through the abdominal wound. Granulations touched with nitrate of silver. On the fifteenth day, wound entirely closed; urine passes *per viam naturalem*; appetite

and spirits good. On the twenty-first day animal was killed, and the bladder was found to be firmly adherent to the anterior abdominal wall.

EXPERIMENT II.—Black Newfoundland bitch; weight, 50 pounds; aged four years. Operation same as in Experiment I. Dressings of oakum applied over abdomen. For six days temperature ranged from 102° to 106° F.; pulse, 100 to 145; respiration, 18 to 24. A subcutaneous extravasation of urine occurred, extending to the left mamma, which afterward sloughed, leaving a large granulating surface. The wounds, however, all healed, and on the thirty-second day the animal was killed, and the bladder was found adherent to the anterior wall of the abdomen.

EXPERIMENT III.—Poodle bitch; weight 20 pounds; two years old. Operation same as before. Sutures held for three days, after which healing by granulation. Dog seemed in good health and spirits throughout. Fistula closed completely in ten days. Killed on the twenty-first day; bladder found attached to the anterior abdominal wall.

EXPERIMENT IV.—A cross-bred setter bitch; four years old, and weighing 40 pounds; in poor condition at the time of operation. Was fasted for twenty-four hours, and operated upon under the carbolic spray. The operation was performed as in the previous cases. Four interrupted sutures of carbolized silk were used, and no dressing of any description applied; a harness was immediately put on, so that she could not bite the part, or tear the stitches away. Was then put in a dark place and left alone for twenty-four hours. When visited was somewhat stupid from the effects of the anæsthetic, and seemed unwilling to eat or drink. The pulse and temperature were normal, and the respiration a little below normal. The wound looked healthy; there was some inflammatory swelling, but no discharge of urine through the incision. As far as could be seen no urine had been passed; a catheter was carefully introduced, and about one and a half ounces of high-colored urine was withdrawn. Nothing was done to the wound except to spray it for a few minutes with carbolic solution. On the third day she drank a little beef soup, appeared quite in her usual spirits, and passed her urine at two different times. On the fifth day the stitches were removed, and she was given her freedom and a generous diet, together with gentle exercise. The wound has entirely healed by first intention, and there has been no escape of urine through the incision. Was allowed to run about the infirmary for a week, and was then destroyed. Autopsy showed firm adhesions between the bladder and the abdominal walls. The bladder was healthy, and showed slight thickening at the point of incision.

EXPERIMENT V.—A white bull bitch; six months old, and weighing 20 pounds; in good condition. She was prepared and operated upon as in the first case, and placed under the same conditions of quiet and fasting. The wound healed by first intention in the anterior two-thirds, the remaining third by granulation. The reason of this partial failure was due, most likely, to the suture being tied too tightly. There was no escape of urine from the wound at any time, the animal voiding her urine naturally. She was kept ten days after healing had taken place, and then destroyed. The autopsy showed firm adhesion of the viscus to the abdominal walls. The bladder itself was hypertrophied, enlarged, and flabby, but otherwise healthy.

EXPERIMENT VI.—A black and white cur dog; two years old; weight, 49 pounds; in good condition. Before opening the bladder a perineal incision was made to facilitate the introduction of a catheter, which was afterward retained in place by stitches taken in the surrounding skin. The abdominal incision healed by first intention. The perineal wound was nearly four weeks in closing, the urine constantly dribbling away, until healing took place. On post-mortem examination the bladder was found to be firmly united to the line of the abdominal incision. The

urethra was constricted to about one-half its natural size where it had been opened.

EXPERIMENT VII.—A hound; liver and white; seven or eight years old; weight, 49 pounds. The operation in this case was a repetition of the previous one, except no catheter was allowed to remain. Healing with first intention took place in the abdominal incision in four days. The perineal incision healed by granulation, and the urine, after the third day, escaped by its natural outlet. Adhesions were well established in this case and the bladder and urethra were healthy.

EXPERIMENT VIII.—A partly bred Gordon setter bitch; nine months old, and weighing 53 pounds; plethoric. This patient required an unusual amount of ether to effect anæsthesia, and during the operation artificial respiration had to be performed. The following day the temperature was elevated to 105° F.; pulse, 120; respiration, 60. There was much inflammatory swelling about the wound, with a slight discharge of urine. A catheter was introduced, but it gave rise to so much irritation that it was not allowed to remain. For more than a week the temperature was from 105° to 101° , the animal having no desire to eat, but showing intense thirst. A fistulous opening was present, through which the urine escaped continually. This remained until she was destroyed, twenty-five days after the operation. Autopsy showed adhesions more marked than in any of the other cases, and a fistulous tract, large enough to admit a silver probe, leading from the bladder to the surface.

The bladder in the dog is covered on all sides by peritoneum, hence our operations were intra-peritoneal. In Experiments I., II., and III. we did not succeed in getting union by first intention. After three or four days the sutures gave way, and healing went on by granulation, with escape of urine from the abdominal wound. Nevertheless, it was gratifying to note that adhesions preventing the escape of urine into the peritoneal cavity had already occurred thus early, and rapid closure of the fistulous tracts ensued. In Experiment V. two-thirds of the incision healed by first intention. In Experiments IV., VI., and VII. healing occurred throughout by first intention. In Experiment VIII. a fistulous tract remained, sufficient to admit a silver probe, and it is to be regretted that no attempt was made to close the same, which undoubtedly could have been effected without difficulty by the application of a suture. It may therefore be said that our experiments have been uniformly successful. In all the cases firm adhesions between bladder and anterior abdominal wall were found to exist. In the first two cases the dressings applied were practically useless, and in the subsequent experiments no dressings were used, the wound in each being occasionally irrigated with carbolized water. A catheter could be retained in only two of the dogs, and that with difficulty for but a short period. We observed that in nearly all the cases some hypertrophy of the bladder-walls was manifest, induced, no doubt, by the abnormal attachments of the viscus.

It is true that the peritoneum in the dog is very tolerant of injury, but not much more so than that of man, as abdominal surgery has long since demonstrated that the danger to life from injury to the peritoneum, so long as no decomposable or septic fluid escapes and remains in its cavity, is very slight indeed.

It is obvious also that the conditions of position, mode of life, etc., of the animals experimented upon are such as would militate against, rather than favor the success of such an operation, while in man, quiet, recumbent posture, constant drainage of bladder by catheter, Listerism, etc., are available factors which will contribute no little to the safe and rapid union and healing of a cysto-abdominalraphy.

A Boy describes the method of extracting a tooth in this way: "The doctor hitched fast to me, pulled his best, and just before it killed me the tooth came out."

INFUSION OF THE LICORICE BEAN (JEQUIRITY, ABRUS PRECATORIUS) IN THE TREATMENT OF INVETERATE PANNUS.¹

By EMIL GRUENING, M.D.,

PROFESSOR OF OPHTHALMOLOGY NEW YORK POLYCLINIC.

THERE are conditions of vascularity and infiltration of the cornea which resist every mode of treatment, remedial as well as operative. As a last resort in these desperate cases of trachomatous pannus, inoculation of the eye with blennorrhoeic or gonorrhoeic pus has been proposed, and in a number of cases successfully practised. The purulent inflammation of the conjunctiva following this mode of inoculation often destroys the granulations of the lids and clears the opaque cornea. In spite of such favorable results, the treatment of pannus by inoculation has not been generally adopted. Many surgeons are strongly opposed to it, and base their objections upon the following arguments: 1, the introduction of pus, especially gonorrhoeic pus, into the eye of man, is in itself a revolting procedure; 2, the ensuing ophthalmia often gives rise to diphtheritic infiltration, which may destroy the eye; 3, the patient may become infected with syphilitic virus from urethral chancre; or, 4, may become affected with gonorrhoeic arthritis.

This array of facts and possibilities is sufficiently potent to deter both the physician and the patient.

Quite recently de Wecker, of Paris, published an account of a new method of rapidly causing purulent, or rather croupous, ophthalmia in cases of inveterate pannus. This method is said to possess all the advantages of inoculation, but none of its repugnant and perilous features.

De Wecker experimented with an infusion of jequirity, or licorice bean, the seed of *abrus precatorius*, a shrub belonging to the order of Leguminosæ.

The infusion was prepared in accordance with a formula extensively used among the natives of Brazil. The formula reads as follows: Pulverize thirty-two beans, macerate them in five hundred grammes of cold water during twenty-four hours, then add five hundred grammes of hot water and filter immediately after cooling. Brushed upon the inner surface of the lids, instilled into the eye, or applied on linen compresses to the outer surface of the lids, this infusion produces, within a few days, a most decided croupous or purulent conjunctivitis, which, after the discontinuance of the irritating agent, rapidly subsides, leaving a previously trachomatous lid without any trace of granulation, and a previously opaque cornea without a vestige of infiltration and vascularity.

The gratifying results obtained by de Wecker in his cases of chronic granulation and corneal opacity induced me to employ the infusion in a few cases of inveterate pannus. Several years ago a friend had sent me from the West Indies a small quantity of the very pretty coral-like licorice bean, and as I was still in possession of the seeds, I ordered an infusion to be prepared according to the Brazilian formula given above. This infusion proved to be perfectly inert. My results were negative and are recorded as such in the Transactions of the New York Ophthalmological Society.

Inasmuch as these negative results might have been due to the age of the bean employed, I procured an infusion prepared of fresher seeds, and admitted, for the purpose of experimental study, two cases of granular lids and inveterate pannus into the eye wards of the Mount Sinai and the German Hospitals.

The first case was that of a little girl, ten years of age, who had suffered from trachomatous pannus for a number of years, without being benefited either by the perennial application of sulphate of copper or the operations of canthoplasty and peritomy.

The second case was that of a man, fifty-five years of age, who had been treated eight months with sulphate of copper in substance and the mitigated stick. His pannus was very dense, and he suffered greatly from photophobia.

The patients were treated in the following way: The infusion of licorice bean was freely applied by means of a camel's-hair brush upon the inner surface of the upper and lower lids three times daily. The application is painless. Compresses moistened with the infusion were placed over the eyes and kept in position day and night. This treatment was continued five days, during which time the man suffered from frontal headache, loss of appetite and sleep, while the child remained perfectly well, and neither of the patients exhibited any rise of temperature. With regard to the local changes observed in the course of the treatment, I may mention that during the first twenty-four hours no alteration was perceptible, but that on the third day the lids were found to be much swollen and their conjunctival surface covered with a yellowish-white membrane, which adhered firmly in the upper and but slightly in the lower lids. The cornea had become much more opaque through an increase of vascularity and infiltration. On the fifth day, when the treatment was discontinued, all the changes had become still more pronounced. I then ordered cold applications and instillation of a saturated solution of boracic acid, and, to my intense gratification, found that the improvement in the condition of the eyes, following the jequirity treatment, was so rapid and satisfactory that both patients could be discharged ten days later. The inner surface of their lids had become smooth and shining and the vascularization and infiltration of the cornea had completely disappeared.

These two cases fully corroborate the glowing account given by De Wecker of the action of jequirity upon inveterate pannus. The limited experience thus gained is most encouraging, and it seems probable that in this infusion of the licorice bean a specific has been found for a class of cases that hitherto resisted every mode of treatment. More experience, however, is needed. Gentlemen who have pertinent cases and wish to experiment with jequirity can procure the fresh bean or the infusion from Mr. Fingerhut, druggist, corner Twenty-eighth Street and Fourth Avenue, New York City.

ENCEPHALOID SIMULATING SUBCLAVIAN ANEURISM—LIGATURE OF RIGHT SUBCLAVIAN IN SECOND PART OF COURSE.

By HENRY E. JONES, M.D.,

PORTLAND, OREGON.

(Reported by F. B. EATON, M.D.)

SURGICAL literature, and especially periodic literature, has chronicled a few narratives illustrating the unusual difficulties involved in the differential diagnosis of aneurism when the existence of a tumor is suspected. No form of tumor presents so many diagnostic difficulties as encephaloid, and perhaps in no part of the body are these difficulties so great as in the posterior triangles of the neck.

The following history and operation will attest these statements, as well as the unreliability of the history itself, so much depended upon as a means of diagnosis. Moreover, it will serve to emphasize the warnings so often repeated in the text-books, while it proves their limitations in practice:

K—, aged forty, an American backwoods farmer, consulted me October 15, 1882. He had been a hard worker, for the past five years, at wood chopping. A year ago he first felt pain in the right shoulder, and supposed it to be rheumatic. Two months ago he first noticed a lump had formed over the right collar-bone and attributed its appearance to lifting. It throbbed when first noticed, this throbbing being increased by fast walking and work. Four weeks ago he consulted two physicians, who said they heard a "bruit" and saw the lump pulsate, which pulsation was apparent to himself also. The last time it pulsated was three weeks ago, when, while fixing a fence, he suddenly felt something give

¹ Read before the New York State Medical Society, Albany, February 6, 1883.

way in the region of the tumor, and experienced such severe pain that he could not rest. Heat and rubbing allayed the pain somewhat. Family all healthy excepting an older sister, who, however, had no trouble of this nature.

The patient was a healthy, robust-looking subject, with a fine color and complexion, the very opposite of cachectic, the expression of the face being, however, a little drawn and anxious. The right clavicle was displaced upward, and behind and above it was a somewhat firm swelling, extending about two inches posteriorly to the clavicle. Below the clavicle, and occupying nearly the whole pectoral region of that side, was a round swelling, plainly continuous with that above the clavicle, measuring seven inches in diameter and extending from the inner border of the deltoid nearly to the sternum.

In the cut the tumor is too heavily shaded, and the right clavicle not elevated as it should be.

One or two subcutaneous veins were faintly seen over the centre of the convexity. It was soft and elastic to the touch, having a cystic feel, but there was no fluctuation, neither was there discoloration of the integument or enlargement of glands. The appearance of the swelling and venous injection gave me, at the first glance, the impression that here was an encephaloid, but learning that a *bruit* had been heard, and in consideration of the history, I advised perfect rest, in order that the diagnosis might more readily be ascertained. Accordingly he was put to bed and quiet maintained. The pain now increased, apparently as a result of the confinement. After ten days there was no marked change to be noticed in the tumor, only a slight enlargement and some flattening. Deep pressure over the second portion of the subclavian controlled the pulse, but caused no perceptible difference in the tumor.

The question of diagnosis now lay between a diffuse aneurism and a tumor; the presumption being, from the sudden disappearance of pulsation during exertion, that it was the former.

An operation was decided upon as the only course now open.

On the day of its performance the temperature was 101° . My purpose was to expose the subclavian in the second part of its course, and, throwing a ligature around it at a sufficient distance from the tumor to fulfil the Hunterian principle (leaving it untied), to explore the swelling by incision. My assistants, however, arrived so late and the operation proved so difficult from the cla-

vicular displacement that the winter twilight of this northern latitude was upon us by the time the ligature was around the artery. It was decided, therefore, to tie the artery, which was done directly behind the outer edge of the *scalenus anticus*. The ligature controlled the pulse perfectly, and the wound was closed by sutures and dressed antiseptically.

The tumor was then explored by plunging a hypodermic needle and syringe into the apex of the tumor and a small amount of half-clotted blood was withdrawn. The patient reacted well and collateral circulation was evidently soon established, as the arm remained warm. The temperature for three days remained uniformly at 101° , the only symptom of note being pain of some severity in the right side of the neck above the wound.

On the morning of the fourth day the temperature rose suddenly to 104° , and heavy sweating ensued. The case presented now all the symptoms of septicæmia, though the wound had been kept carefully cleansed, and the patient died on the night following the sixth day with a temperature of $107\frac{1}{2}^{\circ}$.

Autopsy.—Twelve hours after death.—Several of the sutures had cut through and pus had formed in the wound, burrowing a short distance up the side of the neck. An incision was made over the most prominent portion of the swelling, exposing the pectoralis major, which was cut and reflected. The pectoralis minor was found much stretched by the underlying prominence, but on dividing and reflecting it, it was found to have no connection with it. The tumor as now exposed was found to be a large encephaloid, lying freely within, and filling nearly the whole pectoral region, as well as a portion of the axilla, extending as far back as the anterior edge of the latissimus dorsi. Upward it extended under and above the clavicle, which was considerably displaced. Its upper and inner extremity touched the scalenus anticus, about one-third of its bulk being above the clavicular boundary line. In the vicinity of the wound the tumor had, as a result of the operation, sloughed considerably. The artery was found to be plastically occluded; the ligation correct and complete.

The tumor was dissected out completely, and on passing a catheter through the axillary end of the artery, the latter was found to pass through the substance of the tumor, while dissection proved the vessel not to be included in the morbid process. The most prominent portion of the mass which had been aspirated was found softened and full of black blood. The pleura and pulmonary tissue were normal.

Remarks.—A due consideration of the patient's history and symptoms, and of the position and attachments of the tumor will make it apparent that diagnostically this case is instructive as well as interesting.

To illustrate one remarkable simulation of aneurism which this tumor affords, it may be cited that in placing the ligature and clearing a space with the fingers for the aneurismal needle, the portion of the tumor touched had a "feel" precisely similar to that of a *sac* containing blood. But more particularly the case serves to demonstrate the unreliability of the so-called "scientific tests" of aneurism, as well as the tendency of the patient's own history to mislead. This patient was of unimpeachable honesty and intelligence. The tumor was in the course of a large artery when it first appeared. Two physicians, one known to myself as thoroughly competent, hear a "bruit," and see the pulsation; the latter ceases suddenly with the exact symptoms attending the formation of a diffuse aneurism. In addition there was neither cachexia nor glandular infection. My first opinion, partly intuitive, proved correct, while the careful application of systematic methods of diagnosis by myself, and by several very competent surgeons in consultation, only served to mislead. The negative result of aspiration by a fine needle hardly coincides with Gross' assertion of its value in such cases. He says (vol. i., p. 717, fifth ed.): "When no satisfactory decision can be arrived at, the

only resource is the insertion of a delicate exploring needle, which, while it can do no harm, if it be properly employed, will at once determine the diagnosis." Here the half-clotted blood withdrawn only obscured correct diagnosis.

Where the diagnosis remains doubtful it certainly seems wise to expose the artery, adjust the ligature untied, and then make an exploratory incision of the tumor.

Reports of Hospitals.

ST. FRANCIS HOSPITAL, NEW YORK.

SERVICE OF C. LELLMAN, M.D.,

(Reported by WILLIAM D. DIETZ, M.D., House Physician.)

CASES OF TYPHOID FEVER.

SINCE October 1st, the commencement of the writer's term as House Physician at St. Francis Hospital, there have been treated in the service of Dr. Lellman, thirty-one cases of abdominal typhus. A short epitome of the histories of some of these may prove of interest as illustrative of various manifestations of the malady. In six instances the disease terminated fatally; one patient being brought in moribund, and dying in short time.

CASE I.—*Typhoid fever—Pulmonary infarction—Pneumonia—Pulmonary abscess—Pyo-pneumothorax—Femoral embolism.*—Anton H—, aged nineteen, wig-maker. Initial chill, September 22d; admitted September 25th. The symptoms were of moderate intensity, and under expectant treatment the patient soon improved. On October 1st, the morning and evening temperatures were 99°; the diarrhoea had ceased, the bronchitis disappeared, and the patient complained merely of weakness. On the 7th, however, the morning temperature was 104°, and signs of an incipient pneumonia, involving posteriorly the lower portion of the left upper lobe, were present. The inflammatory process was regarded as of embolic origin, and embolism of other parts of the body was anticipated. On the 8th, a pulmonary hemorrhage took place, which recurred with less intensity on several subsequent days. A week later, sudden pain was experienced in the right inguinal region, extending from there along the course of the femoral artery; the limbs felt cold and numb, and the vessel imparted the sensation of a hard cord in Scarpa's triangle. An occasional feeble pulsation could be detected at Poupart's ligament, but below this point none. Meanwhile, the pneumonic process had extended, and had gone on to the formation of an abscess. The pleura was perforated, and pyo-pneumothorax established, to which the patient succumbed October 19, 1882.

CASE II.—*Typhoid fever—Catarrhal pneumonia—Femoral embolism.*—Max W—, aged twenty-six, miller. Initial chill, October 20th; admitted October 26th. The disease at first ran the course of an ordinary typhoid attack, exhibiting intermittent thermometric fluctuations in the fourth week. On November 18th, the morning temperature was 99°. Later in the day the patient complained of great pain in the right side, and presented signs of a beginning inflammatory process of the base of the right lung. On November 19th, the temperature was 103° in the morning, and 105° in the evening. The pneumonia extended until it involved the right lung below the middle of the fourth rib anteriorly, and the eighth posteriorly. In the course of this complication the patient complained of pain in the left groin and region of the femoral artery (December 10th). Pulsations in the vessels were found to be feeble and diminished in number at Poupart's ligament, and absent in Scarpa's triangle, in which situation the artery was rigid to the touch. The limb felt numb, and its temperature was lower than that of the other side. By December 24th, all pulmonary symptoms had disappeared, but collateral circulation had not yet

been perfectly established through the right lower extremity. January 24th: The patient has entirely recovered with the exception of a certain amount of swelling of the left lower extremity.

CASE III.—*Typhoid fever—Double catarrhal pneumonia—Otitis media.*—Annie H—, aged fifteen, domestic. Initial chill, November 27th. Eruption on the tenth day. The attack was a very severe one, and utterly prostrated the patient, an anæmic girl, in a short time. For quite a period she lay at the point of death, in a condition of stupor, low, muttering delirium, and extreme subsultus. December 21st: Temperature, 8.30 A.M., 98°; 7 P.M., 101°; 9 P.M., 105°. About 9 P.M. she had several marked chills, the first indications of a pneumonia which was to involve both lungs posteriorly from apex to base. By January 5th the right lung, and by January 17th, the left, had returned to their normal condition. An otitis media developed itself on January 1st, but yielded to treatment in a few days. February 1st. The patient has entirely recovered.

CASE IV.—*Typhoid fever—Intestinal hemorrhages—Paralytic dysphagia—Epistaxis—Otitis media.*—George E—, aged twenty, tailor. Initial chill, September 18th; admitted October 2d. A few days after admission the patient had several profuse intestinal hemorrhages, which jeopardized his life and served to increase an already existing anæmia. Six weeks later, after the subsidence of the typhoid symptoms proper, a paralytic dysphagia manifested itself, the patient speaking in a thick unintelligible, nasal voice, and complaining that he could not swallow unless lying down, and that ingested fluids occasionally passed out through the nostrils, or into the larynx. At the same time he suffered from epistaxis to such a degree as to necessitate the adoption of active measures for its prevention. As a result, possibly, of the entrance of ingesta into the unguarded Eustachian tube, an otitis media developed (December 14th), which gave rise to great pain and tenderness, hemicrania, profuse purulent discharge, and considerable elevation of temperature. On January 11th, deglutition was easier, speech more distinct, and the otitis had disappeared. The patient thereafter gained rapidly in weight, and by January 16th was without fever, and could talk and swallow as well as ever. He is now, February 1, 1883, entirely cured.

CASE V.—*Typhoid fever—Parotitis.*—W. F. G—, aged seventeen, clerk. Initial chill, October 11th; admitted October 23d. The course of the disease was quite a severe one. The intermittent stage was reached on November 6th. Two days later, however, the morning temperature was 105°; the patient experienced a chill of extraordinary severity, complained of pain and tenderness in the parotid region, and soon became delirious. Well marked swelling of the gland occurred, and in the evening the temperature rose to 106½°. On November 9th, the temperature in the morning was 104¾°, and in the evening 106°. On November 10th, it was 104½° and 106° respectively. The patient succumbed from exhaustion, at 10 P.M., November 10th.

CASE VI.—*Pneumotyphus.*—Ludwig J—, aged fifteen. The initial chill occurred on November 14th, and the characteristic eruption appeared on the fifth day. The evening temperature of the last six days of the first week was uniformly 105°. Throughout the course of the disease there was no diarrhoea, the bowels being rather inclined to constipation. The bronchial manifestations, on the other hand, were exceptionally severe, bronchitis occurring early, and soon associating itself with pulmonary collapse and intense hypostasis. By December 1st, all bronchial symptoms had subsided, and by the middle of the month the patient had entirely recovered.

CASE VII.—*Abortive typhoid.*—George O—, aged twenty-eight. Initial chill October 30th; admitted November 4th. The eruption and the early manifestations were those of the "normal" typhoid of Niemeyer; but the highest temperature observed, on the seventh day,

was 103 $\frac{3}{4}$ °. In the second week there was but a slight bronchitis, and the abdominal symptoms had entirely subsided; the highest temperature attained was 104°. In the beginning of the third week convalescence was established, and the patient went on to his final recovery without untoward accident. He left the hospital December 18th.

CASE VIII.—*Typhoid fever—Croupous pharyngotonsillitis.*—Robert B—, aged thirty-four, singer. Was taken sick on November 30th, and admitted December 16th. At the time of admission, the abdominal and bronchial symptoms had ceased, but the patient was utterly prostrated. A croupous exudation involved the pharynx, tonsils, the hard and the soft palate. In spite of energetic stimulation, the heart gradually gave out, and the patient died nine days after admission. The autopsy showed recent typhoid intestinal ulcerations.

Progress of Medical Science.

THE MORTALITY REFERABLE TO ALCOHOL.—At the end of a long and carefully prepared report recently drawn up by a committee of the Harveian Society, it is concluded that there is, upon the whole, reason to think that, in the metropolis, the mortality among any considerable group of intemperate persons will differ from that generally prevailing among adults in the following important particulars, viz.: a fourfold increase in the deaths from diseases of the liver and chylipoietic viscera; a twofold increase in the deaths from disease of the kidney, a decrease of half as much again in those from heart disease, a marked increase in those from pneumonia and pleurisy, a considerable increase and an earlier occurrence of those from disease of the central nervous system; a marked decrease in those from bronchitis, asthma, emphysema, and congestion of the lungs, a decrease nearly as great in those from phthisis, and a later occurrence, or at least termination, of the disease; a very large decrease of those from old age, with an increase of those referred to atrophy, debility, etc., and the addition of a considerable group referred in general terms to alcoholism or chronic alcoholism, or resulting from accidents.—*British Medical Journal*, February 3, 1883.

NOCTURNAL ENEURESIS, TREATED BY VOLTAIC ALTERNATIVES.—Dr. Althaus writes, *British Medical Journal*, February 3, 1883: "In June, 1882, I was consulted in the case of a boy, aged fifteen, who had suffered from incontinence of urine during sleep, ever since he was nine years of age. He had been treated with belladonna and other medicines without relief; and as he was about to enter a public school, where a continuance of this trouble might have been particularly annoying, the parents were very anxious that something more should be done. The boy's general health was good, but he was considered a nervous child, and highly sensitive. There were no ascarides, but he had a very long prepuce which could only with difficulty be retracted. There was, however, no suspicion of masturbation. Treatment by electricity having been recommended, I applied the middle-sized circular cathode over the region of the bladder, and the large oblong anode (five inches by two) to the lumbar portion of the spine. The current-strength 2.50 milli-amperes for five minutes at a time. As after a few such applications no material benefit appeared to have been gained, I then added fifty voltaic alternatives produced in the metallic circuit. The night after this was free from the usual annoyance, and the boy has made an apparently uninterrupted recovery." Dr. Althaus prefers this method of treatment to injections of nitrate of silver, as recommended by Sir Henry Thompson. He believes that belladonna is of value when eneuresis is distinctly caused by undue excitability of the bladder.

COMPOUND FRACTURE OF THE FEMUR, Erysipelas, PYÆMIA—AMPUTATION OF THE THIGH—SUBSEQUENT EXARTICULATION AT THE HIP—COMPLETE RECOVERY.—Barker describes a case under this title at great length. The patient was a rivetter, aged twenty-nine, who fell from a roof and fractured his femur. The case illustrates, in the first place, what is, however, unfortunately rare in experience, namely, the possibility of recovery from pyæmia, even in a patient weakened by a most severe injury, prolonged suppuration, and an attack of erysipelas. Secondly, it illustrates the feasibility in some cases of amputating with the best results through the thigh for compound fracture, leaving a second compound fracture in the neighborhood of the hip-joint to be treated otherwise later on, when the first amputation wound is healed. Thirdly, it shows that, in such a case, it is possible to exarticulate the whole of the remaining bone up to the hip-joint, without re-amputation through the soft parts, but through a moderate opening in the outer side of the stump.—*British Medical Journal*, February 3, 1883.

SALICYLATE OF SODA IN ACUTE ORCHITIS.—Dr. Henderson, of Shanghai, reports (*Lancet*, December 16, 1882) three cases of gonorrhœal epididymitis in which the symptoms were rapidly relieved by salicylate of soda. In using it, Dr. Henderson advises that only acute cases, i.e., those in which there is distinct rise of temperature, be selected. The dose should not be less than twenty grains, repeated every hour until at least three doses have been taken. Afterward the drug is to be given at longer intervals.

A NEW TREATMENT FOR GONORRHOEA.—A correspondent writes to the *Lancet* concerning what he considers a rational treatment of this common affection. He gives regularly five-grain doses of iodide of potassium, and full doses of cubeb in powder, every three hours. The cubeb in drachm doses he finds rarely fails to cut off the ailment rapidly, and the iodide, besides its solvent influence on the essential element of the powder, has a well recognized action on the various mucous surfaces.

ELECTRICITY IN INTERMITTENT FEVERS.—The treatment of intermittent fever by electricity in the Medical Clinic of Genoa, directed by Professor de Renzi, has given very good results (*Annali Univer. di Med.*). Electricity was first tried in the treatment of intermittents by Frank and Borsieri, afterward by Aldini, Cavallo, and Puccinotti, and lately, after having been neglected for a long time, by Bossi, of Rome, Sini, of Leghorn, and by Shipulski, Deparquet, etc. In De Renzi's hands it gave immediate and decisive results. He says that in the majority of cases intermittent fever can be cut short more promptly than by quinine. In nine cases he had five complete cures, one marked improvement, one slight, and two unsuccessful cases. He uses the constant and the faradic currents; the constant applied for five to fifteen minutes in ascending direction along the spinal column, the rheophores being placed over the two extremities of the medulla; the faradic of medium intensity for half an hour, the patient holding a rheophore in each hand. The faradic was more efficacious than the constant current.

FREQUENT TAPPING IN ASCITES.—Mr. Paterson, in the *Lancet*, December, 1882, mentions a case of cirrhosis of the liver in a woman, aged forty-two, in which he tapped the abdomen with a small canula thirty-nine times in eight months, drawing off altogether one hundred and ten gallons of fluid. The treatment, however, was only palliative.

THE THERAPEUTIC USE OF CLAY.—Dr. Saveljeff, of Vladimir, confirms the results published by Drs. D. T. Sokoloff (*London Med. Record*, April, 1882) and A. Masalitino (*Ibid.*, November, p. 452). Having followed the advice of Professor Botkin, he has since 1878 employed clay-cakes in about one hundred cases of cardiac organic

diseases, cardiac neuroses, and palpitations, of every kind, and invariably met with most remarkable success. He takes common red clay (instead of Sokoloff's sculptor's clay, or Masalitinoff's plaster of Paris), moistens it with water until a thick paste is formed, makes a cake of a palm's size and of a finger's thickness, and then applies it to the cardiac region. Pain disappears within eight to ten minutes, palpitation within ten to fifteen. A cake dries in feverish patients in two to three hours, otherwise in five, and then is to be changed. In conclusion the author states that the Vladimir peasants from time immemorial have employed red clay-cakes (all over the body) as a cooling remedy in febrile cases of every description.

THE SALICYLATES AND HEMORRHAGES IN TYPHOID FEVER.—In the *British Medical Journal* Dr. Fergusson calls attention to the increased frequency of hemorrhages, which he observed in typhoid fever patients treated by the salicylates. He raises the question whether these salts could favor the production of that accident. Dr. Fergusson's successor at an infirmary noticed similar results, following the use of the salicylate of soda. The latter gave ten to fifteen grains of the drug frequently, while Dr. Fergusson exhibited the salt in half-drachm or drachm doses at longer intervals. The question raised by Dr. Fergusson still remains an open one.

DISPLACEMENT OF THE HEART AND SYNCOPE IN PLEURISY.—Dr. Tchirkoff has undertaken a series of experiments on dogs in order to elucidate two points: first, the causes and mechanism of cardiac displacements; and second, the causes of syncope in patients suffering from exudative pleuritis. He has arrived at the following conclusions: 1. In all cases of pleuritic effusion, the first change in the position of the heart consists in a rotatory movement round the long axis from right to left, the apex invariably turning to the right. 2. This rotation depends upon the increased filling of the right side of the organ, in consequence of narrowing of the blood-current in the pulmonary artery. 3. With increase of the exudation and diminution of negative pressure within the corresponding pleura, the difference in pressure between the affected and healthy pleuræ finds its expression in a displacement of the heart toward the healthy side; the displacement to the right (*i.e.*, in cases of left-sided effusion) always being greater and developing more rapidly than that to the left. 4. The apex and the base are displaced simultaneously, but the former in a greater degree than the latter. 5. Positive pressure of an exudation acts only on the distended pericardium and mediastinum, but not at all on the heart itself. 6. Therefore, any extensive displacement of the heart, under the influence of sudden or forcible movements of a patient, cannot take place, for the force of pressure is not excited on the heart, but on various other very elastic structures. 7. In cases of very considerable pleuritic effusions, no rotation of the heart (from right to left) is usually observed; the organ may even appear rotated from left to right under the positive pressure produced by the exudation on the right side of the heart. 8. The sudden death of pleuritic patients cannot be caused by displacement of the heart and sudden compression of the inferior vena cava (as Bartels teaches); for neither experimental cardiac displacements nor a few minutes' compression of the vein in dogs could bring about any attack of syncope; besides, as it is already stated above, any extensive displacement of the heart in a pleuritic patient is impossible. 9. As the author's experiments show, a heart which is exhausted from accommodative work in a case of the pleuritic effusion may be easily and irrecoverably stopped by irritation of one of the vagus nerves; from this experimental fact he concludes that pleural inflammation spreading over the mediastinum may exhaust the heart through directly acting on the cardiac nerves, and so may produce an attack of syncope. According to the author, syncope may occur even in cases of scanty effusion, or after the opera-

tive removal of the fluid and after cessation of the compensating work of the heart. As one of the causes leading to exhaustion of the heart, the author points out an excessive quantity of carbonic oxide present in the blood of pleuritic patients. In conclusion, Dr. Tchirkoff recommends, while operating in empyema, to keep in view that an exhausted heart may be easily stopped in a reflex way, *e.g.*, in consequence of pain caused to the patient.—*London Medical Record*, February 15, 1883.

HYPODERMIC USE OF IODIDE OF POTASSIUM.—Dr. Gilles de la Tourette (*Le Progrès Médical*, January, 1883) draws attention to the hypodermic use of iodide of potassium. He found that it was possible to introduce a syringeful of a solution containing 7.5 grains of iodide of potassium, carefully neutralized, without causing any irritation. In twenty injections, only one caused a slight slough. Some burning pain was complained of, which was usually readily allayed by gentle friction with the palm of the hand. The drug was readily absorbed, and could be detected in the urine on the following day. He thinks the method may be of value where there is intolerance of the drug by the mouth, or in cerebral syphilis with coma and inability to swallow medicines.

CHAMOMILE TEA IN INFANTILE DIARRHŒA.—Dr. Elliot advocates the use of chamomile tea in the diarrhœa of young children (*Practitioner*, December, 1882). The dose, for infants under one year, is one-half to one drachm, and double that quantity for older children, given two or three times a day, or oftener. The rationale of the action is the power the drug possesses of subduing reflex excitability. This power belongs especially to the volatile oil contained in the flowers. A decapitated frog, previously fortified by a dose of chamomile oil, was not susceptible to the influence of strychnia, according to Grisan. He also calmed tetanic convulsions, due to strychnia, by the same oil.

ANEURISM OF THE BRACHIO-CEPHALIC TRUNK CURED BY INJECTIONS OF ERGOTIN.—The subject was one Raphael Beretti. A brother, fifty-four years of age, died of aneurism of the thoracic aorta, diagnosed thirty-four years before death; it gave him no trouble until the last few months of his life. Another brother died of chronic heart disease. In the subject of this history there was developed slowly and unnoticed a diffused true aneurism of the arch of the aorta, of the brachio-cephalic trunk, of the subclavian and right carotid; to this succeeded a false sacciform aneurism of the brachio-cephalic trunk. The cure appeared hopeless, but Dr. Angelini determined to try injections of ergotin, repeated twice a day for a week, then every two days, every three, every five, and so on for about three months. After four months, the aneurism was reduced to half its former size, being hard and firm, and the patient was able to resume work. Dr. Angelini comes to these conclusions: 1. Certain aneurisms, even of arteries of large calibre, of slow growth, can exist unobserved by the patient for many years. 2. Chronic diseases of the arteries, of the cardiac valves, and of the endocardium, have an hereditary predisposition, and are not always due to the abuse of stimulants. 3. His case encourages us to try hypodermic injections of ergotin in all such cases, as well as in aneurisms of small arteries.—*London Medical Record*, February 15, 1883.

INHALATION OF THE SPRAY OF IODOFORM AND TURPENTINE.—De Renzi and Rummo (*Gazz. Medica Ital.*) claim good results in phthisis and other diseases of the respiratory organs from inhalations of iodoform dissolved in turpentine. The patients were made to inhale twice a day for two hours, in a small room, the spray of iodoform and turpentine. The effects were more satisfactory than with any other mode of treatment. There was always prompt and considerable diminution of cough and expectoration: in bronchiectasis the fetid expectoration was completely deodorized. Physical signs diminish, the temperature falls, pulse and respiration are less fre-

quent. The secretion of urea is lessened in proportion to the fall of temperature. Iodoform given by inhalation is much more prompt in action than when taken by the stomach; it is an anæsthetic to the pulmonary vagus, and has an alterative and drying local action, which is aided by the turpentine. Its antiseptic action must also be taken into account.

SURGICAL DILATATION OF THE PYLORUS.—In an individual suffering from pyloric stenosis from a cicatrix, Professor Loreta, of Bologna, after having made an incision in the epigastrium, and opening the stomach, mechanically dilated the pylorus. The result was most successful, since, on the seventh day, the phenomena caused by the stenosis had disappeared, and the patient was going on well in every way.—*London Medical Record*, February 15, 1883.

SOME POINTS IN THE TREATMENT OF CARDIAC DISEASE.—From a number of carefully studied cases of heart disease, Dr. Finny (*Dublin Journal of Medical Science*, February, 1883) draws the following conclusions: 1. That too much dependence is not to be placed on the presence of the physical signs of mitral regurgitation as evidence of organic disease. 2. That such signs may be due to purely functional derangement and weakness of the heart, or to an altered condition of the blood. 3. That blood-murmurs produced in the heart and large vessels may be louder than the murmurs due to valvular lesions. 4. That the danger of valvular diseases is enormously increased by, if not directly due to, weakness of the cardiac walls. 5. That increased action and force of the ventricular contraction in the presence of valvular disease is not to be considered a disease, but rather a symptom of disease, and is directly proportionate to the amount of regurgitation or obstruction. 6. That mitral regurgitation is not to be considered in the light of a "safety-valve function" in cases of aortic obstruction, but as an element of increased danger to life. 7. That lowering treatment of the heart's force is rarely, if ever, required in disease of the organ. 8. That indications for treatment in diseases of the heart should be sought from the evidence of the condition of the muscle of the heart, and not that of the valves.

TWO HUNDRED AND EIGHT CONSECUTIVE CASES OF ABDOMINAL SECTION.—Mr. Lawson Tait gives the following analysis of his last series of operations occurring in the period from March 1 to December 31, 1881: Exploratory incisions, 13 cases with no deaths; incomplete operations, 8 cases, with 4 deaths. Operations for cystoma: one ovary, 36 cases; both ovaries, 28; par-ovarian cysts, 12; hydrosalpinx, 16; pyosalpinx, 20, or 112 cases, 3 deaths. Removal of uterine appendages: for myoma, 26 cases; for chronic ovaritis, 12; for menstrual epilepsy, 1, or 39 cases, 5 deaths. Hepatotomy for hydatids, 2 cases; hydatids of peritoneum, 2; cholecystotomy for gall-stone, 2; radical of hernia, 1; nephrotomy for hydatids, 1; nephrectomy, 1; intestinal obstruction, 1; solid tumors of ovary, 3; hysterectomy for myoma, 10; cysts of unknown origin, 1; tumors of omentum, 1; pelvic abscess opened and drained, 7; chronic peritonitis, 4, or 35 cases, 4 deaths. Total, 208 cases with 16 deaths. These operations were not performed under carbolic spray.—*British Medical Journal*.

CARDIAC GUMMATA.—An instance of this rare occurrence is reported in the *Lancet*. The patient was brought moribund to the hospital. He had seemed well until a fortnight previously, when he began to complain of faintness and pain in the præcordial region. On his way to his work he suddenly staggered and fell, and was unconscious till death. At the autopsy, the heart weighed thirteen and one-half ounces. The pericardium over the left ventricle was studded with pale yellowish-white elevations; there were also one or two over the right ventricle. The endocardium of the anterior wall of the left ventricle was studded with similar nodules. In the

septum was a mass of fibroid tissue extending into the muscular substance, which was permeated by tissue with gummatous characters. The smaller vessels were narrowed by thickening of the intima. The liver had a depressed fibroid scar in the right lobe. The spleen was congested, firm, and adherent to the parietes. The other organs were healthy.

MILK-DIET IN GRAVES' DISEASE.—Dr. Schnaubert speaks very favorably of the value of exclusive milk-diet in cases of exophthalmic goitre. In one of his patients, three weeks' treatment by milk restored digestion and general health, and so greatly improved all symptoms, that some weeks later the patient left the hospital relatively sound, and remained so nearly two years. At this time she returned with highly developed signs of the disease, and though the milk treatment again greatly relieved the patient's condition, she soon died. The necropsy showed hyperplasia in the cervical sympathetic ganglia, pigmentation of roots of the cervical nerves, and cerebro-spinal hyperæmia.—*London Medical Record*, February 15, 1883.

THE SIGNIFICANCE OF CHANGES IN THE PULMONARY EPITHELIUM.—Dr. Veraguth recently completed an investigation concerning the existence and pathological changes of the epithelium lining the pulmonary alveoli. By injecting weak solutions of nitrate of silver into the lung-tissue of healthy rabbits he was able to demonstrate the epithelial lining of the air-cells. This he found to vary in different parts of the lobules. In the terminal alveoli it was made up of small nucleated cells, of a rounded or polygonal shape, while in those air cells which branch from the sides of the bronchi similar corpuscles were collected into little groups surrounded by irregular surfaces of flat, structureless, and unnucleated cells. The composite membrane thus formed was joined directly to the lining of the bronchus.

Veraguth also injected the tracheæ of living rabbits with solutions of nitrate of silver (one-half to four per cent.) and killed the animals after intervals of from six to sixty hours. From observation of the various stages of pneumonia thus artificially produced, he concludes that the origin of fibrin in the croupous exudation is in the destruction of the flat epithelial cells just mentioned. From this he thinks it is fair to assume that in pneumonia of the human subject, the morbid agent, whether infectious or not, produces the same fibrinous degeneration of the unnucleated flat cells.—*Correspondenzblatt für Schweizer Aerzte*.

UNUSUAL MODES OF DISCHARGE OF PUS IN EMPYEMA.—Dr. Bouveret relates a number of cases of empyema in which the discharge of pus took place through unusual channels. He divides these rare cases into two classes. In the first category, the pus works its way into some of the neighboring organs. It may be discharged through the œsophagus, the stomach, the intestines, or the pelvis of the kidney. Or it may force itself into the cavity of the peritoneum or of the pericardium. Such occurrences are so extremely rare that they are seldom diagnosticated during life. In the second class, the pus perforates the posterior cul-de-sac of the pleura and appears in the posterior wall of the abdomen. In such cases the abscess may point in the groin, the lumbar region, the buttocks, or even in the thigh. The prognosis does not appear to be more grave than when spontaneous evacuation occurs through the chest-wall. In case serious general symptoms continue after the discharge of a migratory abscess, the author recommends that the pleural cavity be opened and washed out as in simple empyema.—*Journal de Médecine de Paris*, December 16, 1882.

QUAIN'S DICTIONARY—A WARNING.—On page 1181, article phthisis, the dose of picROTOXINE is given as grain $\frac{1}{6}$ when it should be grain $\frac{1}{60}$.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 17, 1883.

THE CARDIAC MECHANISM AND THE DRUGS WHICH ACT UPON IT.

THE number of nervous centres in or connected with the cardiac muscles has been much multiplied of late years, and is now sufficiently confusing to the ordinary student. These centres have, however, for the mammalian heart in large part only a physiological existence, the exact anatomy not being determined.

The centres whose action is more generally brought out in practical therapeutics are, 1st, two sets of motor ganglia in the heart-muscle, (*a*) one of which (corresponding to Ludwig's ganglion) inhibits, (*b*) while the other (corresponding to Bidder's, to Remak's, and to Löwett's ganglia) excites contractions. In addition, we have the heart-muscle itself, which some drugs seem to act upon directly, either exciting or paralyzing it.

2d. These cardiac centres are connected with three regulating centres, placed in the medulla and upper part of the spinal cord: (*a*) The first of these is the cardio-inhibitory centre, situated in the medulla, communicating with the heart *via* the pneumogastric, and exercising a continually repressive influence upon the rapidity of the heart's beat. (*b*) The second centre is in the upper part of the spinal cord, and it sends weak accelerating impulses to the heart *via* the sympathetic. (*c*) The third is the vaso-motor centre, and it regulates the cardiac action only indirectly. Nerve-fibres pass from the heart to this centre (depressor fibres) which convey impulses depressing it; the blood-vessels dilate and the heart-beat is slowed.

The nervous mechanism of the heart is made up of a fusion of sympathetic and cerebro-spinal fibres and cells, a fact which complicates its study. It should be remembered, however, that the heart beats automatically, and gets most of its motive impulses from local stimuli.

Cardiac tonics, therefore, must act chiefly upon the intrinsic mechanism, stimulating this or that motor-centre according to the morbid conditions. In some cases, however, a medicine may apparently be a cardiac tonic when it really only affects the extrinsic mechanism.

M. Germain Sée has recently written a chapter on cardiac therapeutics in which he gives the following table showing the special action of different drugs on the heart.

	STIMULATION.	PARALYSIS.
Cardiac muscle.	Digitalin.	The same in the second period of action. §
	Iodine in small doses.	Emetin.
	Camphor.	Salts of copper, barium and potash.
	Caffeine.	Chloral in large doses.
		Scillaine.
Intra-cardiac muscular motor centres.		Saponine in its last period of action.
		Iodine in large doses.
Intra-cardiac inhibitory centres.	Muscarin.	Atropin.
		Fabarin.
		Spartine in large doses.
Intra-cardiac ramifications of the inhibitory filaments of the vagus nerve.	Nicotin.	Pilocarpin, second phase of action.
	Pilocarpin.	
	Calabar bean.	
Trunk of the vagus nerve.	Aconitin.	Spartin.
	Nepalin.	Nepalin, second phase of action.
Accelerator filaments of the great sympathetic.	Apomorphin.	Spartin.
Medullary cardio-inhibitory centres.	Digitalin.	Chloral.
Vaso-motor centres.	Bromide of potassium.	Croton-chloral.
		Hydrocyanic acid.

This list is by no means complete. Thus, to the stimulants of the cardiac muscle we must add one or more of the active principles of convallaria, and atropin should be included as a paralyzer of the entire inhibitory mechanism.

M. Sée's table, however, will show that the term "cardiac tonic" is a vague one, and it suggests one important consideration, which is, that in order to study scientifically and carefully the action of drugs on the heart, it is necessary to use the isolated active principles singly at first, and not crude preparations which contain a number of them.

THE SICK IN CASES OF FIRE IN APARTMENT HOUSES

THE recent burning of the Cambridge Flats, in this city, with its attendant loss of life, has called out many comments. One point, however, has been quite overlooked. Of the four persons who occupied the fourth story of the flats in question, the two who failed to escape were sick. The young lady had been suffering from peritonitis and had not yet been allowed to get up from her bed. The mother was a hemiplegic with late rigidity and hardly able to walk. It was owing to these facts more than any others that their lives were not saved.

If one would draw a moral, therefore, it should be that the so-called fire-proof flats should be provided with means for the escape of the sick. A paralytic cannot go down an ordinary fire-escape, and an exhausted fever patient in the upper story of some of our city flats would be almost at the mercy of any accidental conflagration. The precaution of having extra watchmen and extra help during sickness should at least be taken.

We would refer here also to another phase of the matter. It is well-known that many lives are lost simply through the panic occasioned by the fire. This panic could be averted in many cases if persons would only habituate and train their minds to associate the emergency of a fire with a certain definite plan of action. This, of course, would involve a knowledge of all the different modes of egress from the apartments and the house.

THE TREATMENT OF ACUTE RHEUMATISM.

FROM the results furnished by an analysis of a large number of cases of acute rheumatism, met in the primary attack, and treated in St. George's Hospital London, during 1877 and 1878, by Isambard Owen, M.D., as Medical Registrar, much valuable information is elicited as to the merits of the salicylate treatment. These cases, 210 in number, were all recorded under the personal supervision of Dr. Owen, and include all that occurred in the hospital during the years named with the exception of a few which were admitted in the Registrar's absence. The methods of treatment adopted, embraced (a) the salicylate of soda or ammonia in variable doses, alone and in combination with full doses of alkali; (b) the alkalies, or the same in combination with quinine; (c) iodide of potassium, alone or with alkali, bark, guaiacum, or sarsaparilla; and (d) varying treatment. Of those treated by the salicylate, in 85 cases the administration of the drug was commenced in doses amounting to 3 ij. or more in the twenty-four hours; in 52 cases, 3 ij., and in 19 cases, 3 iss. were given during the twenty-four hours. From several tabulated statistics, carefully prepared from these results, it is noticed that a tolerable uniformity exists as regards the average duration of pain and of pyrexia after the commencement of treatment (by salicylate), and that this duration is always independent of the character of the case and of its previous duration. A similar uniformity likewise prevails in the results of all modes of salicylate treatment, showing that the duration of the primary attack was unaffected by the amount of the initial doses of salicylate, or by the combination of full doses of alkali with the drug. A marked excess over these is, however, noted in those cases treated by full doses of alkali alone (or with quinine), the duration of the primary attack being twice as long as under the salicylate. Furthermore, a marked feature of the cases treated by salicylate, especially when administered in large initial doses, is the rapid subsidence of pain and fever, as compared with the more regular decline of these symptoms under other methods of treatment. Therefore, on the average, a duration of a certain number of days under salicylate involves much smaller amount of suffering than the same number of days under alkali.

With the different modes of salicylate treatment, also, the average residence in the hospital (including convalescence) is found to vary, being shorter in cases of low temperature. This total duration is further shown to be independent of the character of the case and of the previous duration, but is favorably influenced by the combination of full doses of alkali with salicylate, more particularly where the latter drug is given in medium dosage; large initial doses tending to prolong convalescence, and small doses showing hardly any greater advantage. And although the primary attack is shortened by the use of salicylate alone, yet the entire period of illness is not lessened by this means. If combined with alkali, however, the advantage gained at the onset is sustained throughout, and most markedly so when, under this plan, the salicylate is given in doses amounting to about 3 ij. in the twenty-four hours.

Regarding relapses, it appears that the tendency is practically the same under either salicylate or alkali, but

that the average duration of a relapse is twice as long, or more, under the former treatment. The combination of alkaline with salicylate treatment apparently exhibited no more effect in preventing a relapse than the salicylate alone. In these cases, however, the administration of salicylate was stopped shortly after the disappearance of pain and fever, hence this conclusion is questionable. Moreover, where salicylate alone was used, pyrexial attacks without pain occurred during convalescence in all cases treated with large initial doses.

The information which these cases offer in regard to the influence of salicylate on cardiac complications is of little or no value. As to the benefit derived from quinine in combination with this drug, the effect is found to be *nil*.

Regarding the use of iodide of potassium and alkali nothing of especial importance is developed. In a few instances this treatment proved efficacious after the total failure of salicylate, and *vice versa*.

From the above, therefore, it will be seen that of these several plans, that which offers the greatest aggregate of advantages is the combination of alkaline and salicylate treatment, the salicylate being given in doses equivalent, at the commencement, to 3 ij. in the twenty-four hours, and reduced as occasion requires.

STATE BOARDS OF MEDICAL EXAMINERS.

WE have always held that State Boards of Medical Examiners are the necessary means to the end of elevating professional standards and nullifying the pernicious effects of our present educational systems. There are, of course, objections to such an idea. These come principally from the smaller colleges, whose standards are low and the chances for whose students in passing an impartial board are comparatively few.

But opposition is not entirely confined to these schools. Many of the larger colleges, or at least such as graduate the largest classes, find it extremely difficult to settle upon any plan that will be practical, and therefore satisfactory to all concerned. There is a good reason for this. It is quite natural for the colleges, great and small, to guard jealously the power they possess to grant licences to practise, without the intervention of State authority. If any college corporation can consider itself the beginning and ending of the law in the matter of licensing, there is not much more for it to desire either in the way of educational influences or business prospects.

We can hardly expect that any school, under the circumstances, will be anxious for any change that may curtail such privileges. When the change comes, it will be the result of compulsion rather than choice. In the meantime general professional sentiment over the country is leaning strongly toward the necessity of the establishment of State Boards of Examiners.

The latest testimony in favor of reform in college examinations comes to us in the scholarly address of Dr. Thomas F. Wood, President of the Medical Society of North Carolina.¹ This gentleman informs us that North Carolina has had a board of medical examiners in successful operation for over twenty years, and as the result

¹Trans. Med. Society North Carolina. Concord, N. C., 1882.

of its workings the character of the profession has been elevated more than by any other means. Public opinion is so much in favor of a law that guarantees proper qualifications according to a fixed standard, that a young physician no sooner settles in any part of that State than the people begin to inquire if he has passed the board of medical examiners. The license of this board is the essential pre-requisite to holding any official medical position for county or State, or indeed to maintaining any professional standing whatever. During the past four years we are informed that candidates have been examined from twenty-three different schools. No preferences are given, no partiality shown. North Carolina has no medical college within its limits, and fortunately is entirely free to protect herself. The results have been everything that could be desired.

A WANT MUCH FELT!

A WESTERN medical journal, whose editors are also professors in a local medical college, claims very emphatically that our country has not medical colleges enough; "and, *it needs more*," says our contemporary, italicizing its disinterestedness and philosophy.

The same journal congratulates the profession upon the organization and success of a new college at Omaha, and of the probable establishment of another new college at Toledo.

We can add to the pleasure of our contemporary by informing it of a report that two new colleges have also been organized in Boston very recently, under the act incorporating manufacturing companies.

It cannot be expected that the great body of the profession feels the need of new medical schools quite so keenly as do those professors who are attached to them. Still the majority is not always in the right, and it may be that new medical colleges are just the things which our beloved country most needs, in order the better to round off its prosperity and accentuate its greatness.

For our part, however, if we could be convinced that legislative codes of ethics had efficacy, we should advocate one that made it not only an ethical offence but a medical crime, to establish cheap two-term schools, ostensibly for the convenience of the community, but really for the aggrandizement of local physicians. We shall gladly welcome and support any new medical college, Western or Eastern, which honestly undertakes the higher medical education. Such colleges are indeed needed; but to say any part of our country wants more of the ordinary kind of Cheap-John educational diploma-factories is a monstrous excursion from the limits of the actual.

THE SIGNIFICANCE OF THE BACILLUS TUBERCULOSIS.

IN the present expectant condition of the profession regarding the significance of the bacillus of tubercle, some experiments by Dr. Franz Ziehl, recently reported at the Heidelberg Medical Clinic, will be of interest.

This gentleman examined the sputa in seventy-three cases of phthisis, and found the bacillus in all instances but one. In some other cases, where a diagnosis of phthisis from physical signs was doubtful, the bacillus was also found. Dr. Ziehl's final conclusions are: First,

that as a rule, the bacillus will be found in the sputa of persons suffering from pulmonary phthisis, but that to this rule there are some exceptions. Second, that the presence of the tubercle bacillus can sometimes be of help in making a diagnosis in early and doubtful cases. Third, that the absence of the bacillus in the sputa will not permit one to exclude phthisis. Fourth, that the number and developmental condition of the bacillus do not furnish (as has been claimed) a basis for prognosis.

There is now considerable evidence, from various sources that the bacillus is less often found in tubercle tissue than in phthisical sputa. Especially is it difficult to find these parasites in the nodules of acute miliary tuberculosis.

A PHILANTHROPIST'S OPINION OF THE MEDICAL FACULTY.

IN the annual report of the American Society for the Prevention of Cruelty to Animals, for 1883, Mr. Bergh gives his views on vivisection, the New York Legislature, and the medical faculty, as follows: "That sum of all physiological villany, vivisection, which I again recommended to the consideration of that sapient State Congress which was characterized by a portion of the press as 'a mob,' has been remorselessly, and, at the bidding of a heartless and opinionated medical faculty, disrespectfully slaughtered as before!" Mr. Bergh may have some kindness of heart, at least for those who agree with him, but he is certainly deficient in common sense to claim that he is the only man on the jury entitled to an opinion. Hence the medical faculty still persist in being stubborn, and of course sentimental humanity suffers.

PRESERVING THE BODIES OF THE DEAD.

MUCH attention is being devoted just now to the best method of preserving the bodies of the dead. The novelty of cremation has somewhat worn away, and though the practice is increasing, it does not seem likely to become popular in the present generation.

The subject of embalming has been most energetically studied by various individuals, largely, we fear, because there is thought to be money in it. Injections and washes containing arsenic or chloride of zinc, form the basis of most of the more common preservative solutions. It has been recently stated that if organic substances are first steeped in an alcoholic solution of nitrate of silver, wiped dry, exposed to the action of hydrogen sulphide, or phosphide, and then immersed in the ordinary galvanoplastic bath, they will keep for an indefinite length of time.

A novel method of preserving dead bodies so that they will not injure the living, has been proposed by Dr. A. Mayer. He advises the use of glass cases, which, after the introduction of the corpse, are sealed and thus made perfectly air-tight. There are two holes in the case. Through one of them carbonic acid gas is forced until all the atmospheric air is driven out. Both holes are then closed. In this way bodies will remain preserved for a considerable time, while their final decomposition can do no harm by polluting the soil. It is not stated whether these coffins can be manufactured cheaply, or whether they would not be liable to become broken and thus valueless.

THE DEATH-CURRENT.

THE current of the Brush-Swan electric light has an electro-motive force of about two thousand volts. It is nearly such a current as would be produced by a battery of two thousand Daniell's cells. Its fatal effects have been shown in several instances already. This current has heretofore been used chiefly in out-door lighting, where the dangerous conductors are beyond reach. It is now proposed, however, to utilize the current in domestic lighting by means of storage-batteries. These batteries, which are contained in large boxes, will be placed in the various houses; they will then be regularly charged by the two thousand volt current, after which they will give off a harmless forty volt current to the house. By this process it is claimed that the terrific and deadly conductors of the principal circuit will be made harmless. It is quite evident, however, that during the time, each day, when the storage batteries are being fed the wires leading to them cannot be touched without dangerous or fatal consequences. It behooves those who have the care of public health, therefore, to watch the introduction of this storage system of lighting, and see that it is done under proper precautions.

In the Edison system of domestic lighting a current is employed of, it is claimed, one-twentieth the "intensity" of the Brush current, and of "lower pressure." The description is somewhat vague, but probably means that the current has a low potential. But assuming it is a current of one hundred volts only, it would still be a disagreeable thing to pass through a fellow-citizen, and it might be dangerous to children. In the introduction of domestic illumination by electricity, the dangers of fire, the danger to the eyes, and the danger to the person or even to life are to be borne in mind.

THE KENTUCKY STATE BOARD OF HEALTH.

THE attention of both the public and the profession has recently been directed to this organization by the secular and medical press of Louisville. The Board was by no means prepared by virtue of past services, efficiency, or judicious management of its affairs to stand criticism or comment, and hence has suffered. Indeed, to those members of the profession cultivating a laudable pride in professional work in behalf of the public, it may be said of the Board, as was said of the defendant in the celebrated Bardell-Pickwick law suit, "the subject presents but few attractions." It has been discovered that one member of the Board has never attended a meeting since the organization of the Board. Another member has not attended for a year or more, and the quarterly meetings of the Board failed for want of a quorum two or three times during the past year. The annual report of last year came out bristling with errors concerning the ordinary lessons of vital statistics, as well as in other matters relating to the public health. The major portion of the appropriation entrusted to the Board goes to the salary and office-rent of the secretary, which official has recently delivered two popular lectures on public health in the State. With this exception the Board has done nothing in the interests of the public health or sanitary science. Very naturally, a bill to increase the appropriation and powers of the Board failed at the last ses-

sion of the General Assembly. In consequence of recent comments and criticisms upon the inefficiency of this organization, a convention of county and local boards was called by the State Board to meet in Louisville on the 7th inst. This convention proved an utter failure. Only ten or fifteen persons were present, and not more than four or five of the one hundred and thirteen counties in the State were represented. The lack of co-operation and confidence thus evidenced by the profession of the State is much to be regretted. It is to be hoped that the Board may by earnest work demonstrate its efficiency, and thereby elevate the cause of sanitary science in the public esteem.

News of the Week.

MORTALITY FROM ABORTION.—A member of the N. E. Divorce Reform League, Mr. S. R. Dyke, states that over six thousand women die yearly in the United States from attempts to destroy unborn children.

A CREMATION SOCIETY IN CHICAGO.—A cremation society, with a capital of \$100,000, is to be formed in Chicago.

THREE DEATHS FROM CHLOROFORM have occurred in Baltimore since October, 1882.

DEATH IN THE DENTIST'S CHAIR.—The wife of a prominent physician of Portsmouth, Va., died March 9th from the effects of chloroform administered previous to the extraction of some of her teeth.

PASTEUR'S REPLY TO KOCH is a long one and somewhat discursive. He answers Koch's charge that he (Pasteur) presented nothing new to science at the Geneva Congress last summer, by citing his communication regarding the mode of attenuating virus and his discovery regarding the special septic effect of hydrophobic saliva.

He says that while in 1877 he (Pasteur) had acknowledged Koch's work upon anthrax, yet Koch himself had never referred to Pasteur's earlier studies in the organisms of fermentation, the diseases of the silkworm, etc. It was he (Pasteur) who made the first discoveries regarding the life histories of these minute organisms. To Koch's charge that pure cultures could not be obtained by the flask method, he states that all the important discoveries and cultivations of minute organisms had been made by this method until recently. He refers to some of Koch's statements as exhibiting "the impertinence of error," and said that "before Koch was born to science" pure cultures had been made and special disease organisms found by numerous experimenters to whom Koch himself was a debtor.

Koch's statements that the anthrax-vaccine is of doubtful value Pasteur characterizes as another impertinent error, and cites some recent statistics from the department of Eure-et-Loire to prove it.

MEDICAL DEPARTMENT UNIVERSITY OF LOUISVILLE.—The Commencement exercises of the Medical Department of the University of Louisville were held last week at Macanley's theatre. The class during the past session was a large one, though the number of graduates

was numerically smaller than that of last year, numbering only about seventy-five. The regular course at this institution now covers a period of six months, and the facilities for instruction, together with the clinical advantages, are in accordance with the advancing standard of medical education in this country. The address in behalf of the faculty this year was delivered by Professor Theophilus Parvin, and was thoroughly scholarly and instructive. This address we learn will be published in pamphlet form.

Both the Kentucky School of Medicine and the Hospital College of Medicine now hold their sessions in the spring and summer months, instead of in the winter as heretofore. The faculties of both these institutions include gentlemen of superior abilities as teachers of medicine, and their duties are discharged with energy and efficiency.

THE BILL TO ESTABLISH A BOARD OF HEALTH IN PENNSYLVANIA is said to have been killed for this session. The bill provided for a mixed board, with homœopaths and eclectics upon it. Opposition was met with, therefore, on the part of the regular profession. We fear that an "unmixed" board cannot be established as long as the atmosphere of Pennsylvania politics continues to be purified and invigorated by that homœopathic statesman, Don Cameron.

THE PSEUDO-BACILLI OF TUBERCULOSIS.—Dr. Schmidt acknowledges, in the February number of the *Chicago Medical Journal*, that the fat-crystals discovered by himself are not the bacilli of Koch. He thinks, however, that, like the true bacillus tuberculosis, the pseudo-bacillus, together with the fattily degenerated cells, with or without pigment, when found in the expectoration of the patient, may prove valuable in the diagnosis of the case; as their presence must certainly indicate grave lesions in the lungs. The particular quantity of fat found in the expectoration of the patient, which may be determined by treating it with the solution of caustic potassa, also may be of service, he thinks, in the diagnosis, as it will indicate the grade of fatty degeneration.

THE TWELFTH CONGRESS OF GERMAN SURGEONS meets in Berlin on April 4th, 5th, 6th, and 7th. The President, Baron von Langenbeck, will attend and preside.

THE SECOND GERMAN CONGRESS OF INTERNAL MEDICINE meets at Wiesbaden April 17th to 20th. There will be a debate upon the tubercle bacillus opened by Rühle and Lichtheim; also a debate upon diphtheria, and one upon the abortive treatment of infectious diseases.

THE TER-CENTENARY OF THE UNIVERSITY OF EDINBURGH will be celebrated in April next. Those acquainted with Edinburgh medical politics state that the glory of Edinburgh medicine and surgery has come from the extra-mural school and not from the University. The former school is said also to be two hundred years older than the latter.

ENGLISH AND AMERICAN MEDICAL STUDENTS.—The total number of first year's students in England, in 1882, was 635. There were 371 of these in the eleven London schools and 264 in the eight provincial schools. Thus England, from a population of 26,000,000, furnishes 635

students yearly, while the United States, from a population of 50,000,000, supplies about 3,500 or 4,000 students annually, or between five and six times as much. Among the four millions of people in the United States between the ages of sixteen and twenty, one in every 1,200 wants to be a doctor.

MODERN THEORIES AND TREATMENT OF PHTHISIS was the title of the Croonian Lectures recently delivered in London by Dr. J. E. Pollock.

THE BOSTON WATER BOARD has been discharged as incompetent to deal with the existing state of affairs.

THE COMMENCEMENT OF THE ALBANY MEDICAL COLLEGE was held at Albany, March 7th. The graduating class numbered fifty-two. Rev. E. N. Potter, D.D., delivered the address to the graduates, and Dr. W. D. Hasbrouck the valedictory.

THE ALUMNI ASSOCIATION OF THE ALBANY MEDICAL COLLEGE held its tenth annual meeting at Albany, March 7th.

A FASTING DOCTOR.—We are informed that a certain Dr. F. T. Cook, of Taylor, Texas, has been outdoing Tanner in the fasting line. On March 3d he had fasted for fifty-five days "with the exception of a pound of soda crackers, a small piece of Graham bread, and an occasional glass of sweet milk"—which are important exceptions certainly. It seems to be a disputed question whether the cause of the fast is a diseased stomach or an affection of the heart. A local paper states that "while the Doctor frankly admits being desperately in love with a certain little lady, still he holds that a man can love on an empty stomach quite as well as he can with one filled with all the luxuries of life."

IN THE CASE OF THE HOTEL BELLEVUE, at Seabright, N. J., recently tried, the jury failed to agree. The main question was whether the sanitary arrangements of the hotel were not so bad that typhoid fever was caused thereby. Most of the expert testimony given was to the effect that the fever had its origin in the hotel. The case will be tried again. It is a most interesting and important one.

SIR ERASMUS WILSON has accepted the position of President of the Egyptian Exploration Fund, and headed the subscription list with a donation of \$2,500.

THE ANNUAL COMMENCEMENT of the Medical School of the University of Maryland was held in Baltimore on March 15th.

THE COUNCILLORS OF THE MASSACHUSETTS MEDICAL SOCIETY have voted that Columbus Medical College be dropped from the list of medical colleges whose diplomas are recognized.

DENTAL SERVICE IN PUBLIC SCHOOLS.—The Municipal Council of Paris has arranged to have a periodical inspection of the teeth (as well as of the eyes and ears) of the pupils in the public schools.

THE PHYSIOLOGICAL PRIZE OF THE ACADEMIE DES SCIENCES has been awarded to M. Dastres.

THE ASSOCIATION OF FRENCH PHYSICIANS meets in Paris on April 1st and 2d. The association is a political one and will do no scientific work.

LOUISIANA STATE MEDICAL SOCIETY.—The next meeting of the Louisiana State Medical Society will be held at Shreveport, La., April 4, 1883.

AN "EXPOSITION GASTRONOMIQUE INTERNATIONALE" is soon to be organized in Paris.

PORRO'S OPERATION IN ITALY.—In a recent letter to the *Lancet*, Dr. C. Godson says that Porro's operation has been performed forty times in Italy, from May, 1876, to February, 1883. Fifteen women recovered, twenty-five died, and thirty-one children were saved.

COMMENCEMENT OF BELLEVUE HOSPITAL MEDICAL COLLEGE.—The annual Commencement of the Bellevue Hospital Medical College took place on the evening of March 14th, at Chickering Hall, and 166 students, comprising the graduating class, received their medical diplomas. The Rev. Dr. Samuel Burchard opened the exercises with a brief prayer. Professor Isaac E. Taylor, M.D., president of the faculty, conferred the degrees. Professor Samuel D. Gross, M.D., of Philadelphia, addressed the graduating class with words of good advice, and Dr. E. A. Morgan, of the graduating class, gave the valedictory.

DR. W. T. BELFIELD, of Chicago, during his visit to this city, has been the recipient of many marked attentions from our leading practitioners, who have been interested and edified by his admirable demonstrations of the different bacilli. We are pleased to announce that his course of lectures, now being published in *THE RECORD*, has given entire satisfaction to his audiences and has realized the best expectations of all who are interested in his line of study. We understand that during the coming week he proposes to accept an invitation to visit Philadelphia and exhibit his microscopic specimens and the different methods of preparing the same. We bespeak for him a cordial reception.

THE INOCULATION OF SCARLATINAL VIRUS AS A PROPHYLACTIC AGAINST SCARLET FEVER.—Dr. Stickler, of Orange, N. J., is making some investigations in the use of equine scarlatinal virus, to test its value as a prophylactic against human scarlet fever. The results will soon be published.

ASYLUM POISONING.—Professor Mallet, of the University of Virginia, has testified that the poison used with such fatal result in the Staunton Lunatic Asylum was aconitine. It is believed that the latter was dropped in the medicine-cups by one of the patients, but the whole affair is still involved in mystery.

ANOTHER ASYLUM TRAGEDY.—On March 10th, at Columbia, S. C., a lunatic in the asylum cut the straps which bound his hands and then attacked a fellow patient, striking him on the head with a heavy piece of wood, inflicting injuries which caused death.

TENEMENT HOUSE CIGARS.—Governor Cleveland has signed the bill prohibiting the manufacture of cigars in tenement houses.

COMMENCEMENT OF UNIVERSITY MEDICAL COLLEGE.—The forty-second annual commencement of the Medical Department of the University of the City of New York was held at the Academy of Music on Tuesday evening, March 13th. Professor Martin opened with

prayer. Ernest R. Birkins, M.D., of the graduating class, delivered a well-written valedictory, and was generously applauded for his effort. Rev. Dr. John Hall in his address to the graduates bade them bring to their life-work rules of honest, conscientious endeavor, to do their best at all times and treat their fellow men fairly, and they would meet with professional and pecuniary success. The prizes were awarded as follows: Gold medal to Robert George Bindrim; silver medal to A. J. Meuer; bronze medal to Frank S. Halsey. Henry P. Loomis, A.B., was awarded a prize of \$500 for the highest standing in the class, and Leroy W. Mubbard gained a prize of \$300 for having passed the best competitive examination in the seven general departments. The honor men are: H. P. Loomis, L. W. Hubbard, W. M. H. McEnroe, M. O. Bunn, F. D. Gray, E. Z. Brievo-gelle, R. E. Bell, E. Le Fevre, G. D. Gregor, O. C. Ludlow. The graduating class numbered one hundred and sixty-four.

Reviews and Notices.

A GUIDE TO THE PRACTICAL EXAMINATION OF URINE. By JAMES TYSON, M.D., Professor of General Pathology and Morbid Anatomy in the University of Pennsylvania, etc. Fourth Edition. Philadelphia: P. Blakiston, Son & Co. 1883.

THE fourth edition of this popular guide-book deserves in all respects the favor which has already been bestowed upon the previous issues of the work. While completeness is not one of the aims of the author, his special object is fully accomplished, viz., to furnish short and precise directions for carrying out urinary analysis in such a way as to satisfy the needs of the practitioner.

THE FUNCTIONS AND DISORDERS OF THE REPRODUCTIVE ORGANS in Childhood, Youth, Adult Age, and Advanced Life, considered in their Physiological, Social, and Moral Relations. By WILLIAM ACTON, M.R.C.S., Late Surgeon to the Islington Dispensary, and formerly Externe to the Venereal Hospital, Paris, etc. Sixth Edition. 8vo, pp. 267. Philadelphia: P. Blakiston, Son & Co. 1883.

THIS little work, which has for so many years been the leading one of its kind on the subject, has just been issued by the Messrs. Blakiston as a sixth edition. The entire field of sexual hygiene and sexual diseases is thoroughly discussed in a calm and philosophic spirit. The general practitioner will find in this interesting volume a safe guide for the treatment of all the affections which belong directly or indirectly to the abuse of the sexual functions.

EARLY AID IN INJURIES AND ACCIDENTS. By DR. FRIEDRICH ESMARCH, Professor of Surgery at the University of Kiel, etc. Translated from the German by H. R. H. Princess Christian. Philadelphia: H. C. Lea's Son & Co. 1883.

IN five short and clear lectures Esmarch shows how non-medical persons may occasionally render great service, perhaps even save a life, in those accidents which are likely to happen at any moment. Popular explanations of medical matters often leave the mind of the lay reader beclouded with doubts and misgivings, or worse than this, may foster the illusive hope that a physician's counsel is needless. No such tendency is attributable to the present collection of essays, and hence the advice found in Esmarch's lectures, if properly heeded, can do no harm, while it may often lead to much good. Of course the physician is expected to be thoroughly fa-

miliar with all this little volume contains, and yet even he may here and there derive a practical hint from a perusal of its pages. Altogether, it is a creditable production, and has lost none of its usefulness in the work of translation.

PROCEEDINGS OF THE NEBRASKA STATE MEDICAL SOCIETY. Thirteenth and Fourteenth Annual Sessions, 1881-82. Omaha, Neb.

BESIDES the usual report of Society proceedings, the views of many of our Western brethren in the different departments of medicine and surgery are recorded in detail, together with some interesting remarks relative to Nebraska, on climate and its relation to disease, and to physical and mental culture.

QUIZ COMPENDS—A COMPEND OF OBSTETRICS. By HENRY G. LANDIS, A.M., M.D. With illustrations. Philadelphia: P. Blakiston, Son & Co.

IN this little book the author has furnished a series of quiz lessons in obstetrics on the system of question and answer. Throughout, while presenting the latest views, etc., he has endeavored to maintain a strict neutrality unbiased by the teachings of various authors. Students will no doubt find this a valuable aid.

A MANUAL OF HISTOLOGY. Edited and prepared by THOMAS E. SATTERTHWAITE, M.D., of New York, Professor of Histological and Pathological Anatomy in the New York Post-Graduate Medical College, etc., in association with Drs. T. DWIGHT, J. COLLINS WARREN, W. F. WHITNEY, C. J. BLAKE, and C. H. WILLIAMS, of Boston; Dr. J. HENRY SIMS, of Philadelphia; Dr. BENJ. F. WESTBROOK, of Brooklyn; and Drs. EDMUND C. WENDT, ABRAHAM MAYER, R. W. AMIDON, A. R. ROBINSON, W. R. BIRDSALL, D. B. DELAVAN, C. L. DANA, and W. H. PORTER, of New York City. Second edition, enlarged and revised, containing two hundred and two illustrations, with an Appendix. New York: W. Wood & Co. 1882.

A SECOND edition of Satterthwaite's manual has quickly followed the first issue. Indeed, the editor informs us that so little time elapsed between the publication of the first and the publishers' call for a second issue, that radical changes have not been introduced in the text. Nevertheless, certain essential alterations have been made, and two appendices have been added to the volume. The first of these is by Dr. W. R. Birdsall, and embodies recent discoveries made concerning the lymphatic system. Dr. E. C. Wendt is the author of the second appendix, which deals with the histology of the salivary glands. His views on several points connected with the subject are at variance with those of many observers. Thus he does not admit the correctness of Boll's statements with regard to the structure of the membrana propria. Boll and others, it will be remembered, describe it as composed of branching cells. Wendt holds that it is merely a nucleated connective-tissue membrane, with superimposed or underlying branching corpuscles, the latter never forming true constituent elements of the membrane in question. He also disputes the presence of capillary secreting ducts between the gland-cells; and further, he is of opinion that the latter are never normally destroyed in the process of secretion.

On the whole it may be said that Satterthwaite's manual worthily represents the histological knowledge of today, and it may be safely used as a guide-book by students and practitioners.

THE ILLUSTRATED JOURNAL OF MEDICINE AND SURGERY. Edited by GEO. HENRY FOX and FREDERICK STURGIS. New York: E. B. Treat & Co. 1883.

THE first number of the second volume of this admirable quarterly, is more than ordinarily filled with good things. It contains excellent articles, beautifully illustrated as follows: Dental Development, by Dr. William Hales, Jr.; Case of Palato-pharyngeal Sarcoma, by Dr. Johnson Eliot; Excision of the Shoulder-joint, by Randolph Wins-

low; Cases of Compound Complicated Hare-lip, by Dr. J. L. Little; Cysto-adenoma of the Thyroid Gland, by Dr. Charles Buckley; Secondary Myeloid Disease of the Pleura and Lung, by Dr. William Osler; Congenital Union of the Fingers, by Dr. J. H. Pooley; A Teratological Contribution, by Dr. George J. Engelmann, and an Apparatus for treating Fracture of the Patella, by Dr. J. S. Wight.

NERVE VIBRATION AND EXCITATION as Agents in the Treatment of Functional Disorder and Organic Disease. By J. MORTIMER GRANVILLE, M.D. London: J. & A. Churchill, New Burlington Street. 1883.

THE use of mechanical vibration in the treatment of various nervous disorders has been placed before the profession for several years. Dr. Granville, now for the first time, however, presents the subject in a complete form, stating the principles and results of the method. We are much impressed with the evident honesty and conscientiousness with which the author of this method puts forth its claims. He has been studying and experimenting with it now for nearly ten years, and he finally submits the facts and hypotheses to the judgment and trial of the medical profession.

Dr. Granville's theory is that the nerve-cell and nerve-fibre, when functioning, are in a state of vibration, the one in its matrix, the other in its partite sheath. In disease, the vibrations are disturbed, weakened, or destroyed. In a beginning sclerosis, for example, the nerve-cell has been prevented from normally vibrating, it atrophies from lack of exercise; in neuralgia, the vibrations passing along the nerve are abnormal in number or rhythm.

The object of treatment by mechanical vibrators is to exercise the cell, or supplant morbid vibrations with others that are either normal or harmonic with the normal.

To secure this, Dr. Granville has, after much experimentation, devised a clock-percuteur, and also a percuteur which goes by electricity, the latter giving much the better results. With these he has a large number of instruments for varying the character of the blow, e.g., discs, brushes, hammers, etc.

The author reports success with the use of his instrument in a large variety of *nervous* diseases: neuralgias, spinal sclerosis, neurasthenia, vaso-motor disturbances, constipation, etc. In some cases of idiocy the application of the percuteur has remarkably developed the intelligence.

Dr. Granville writes, on the whole, quite temperately as regards the new therapeutical method which he has fathered, yet he fails at times to conceal entirely the profound faith which he feels in the great results it will produce.

He applies his vibration theory very widely, and would make it enter very largely into the pathology of all functional nervous diseases.

It appears to us, and we believe it will to every reader, that too much is made of vibrations in physiology or pathology. It is supposed that these vibrations are of *cells* or their vital and organized elements, not of molecules. This is a difficult hypothesis to admit, yet it is not, of course, impossible. A point which is neglected, however, is that of the chemical or nutritive activities of the cells. These, in functional disease, are undoubtedly altered, and there must be more important and fundamental factors in disease than mere vibrations, which must, if they exist, depend upon them.

As for the practical part, there is no question that good results can be obtained by mechanical vibrations. The method has been employed in Paris by Boulet, and also in New York, with as yet no definite results.

CASTOR OIL AND GLYCERINE.—Dr. William Soper claims that glycerine increases the purgative power of castor oil when given with it. A preparation combining, but not mixing these two, is active in teaspoonful doses. —*Lancet*.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 14, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

(Continued from p. 277.)

CARDIAC DISEASE—THORACENTESIS—DEATH.

DR. VAN SANTVOORD presented specimens accompanied by the following history: They were removed from the body of a man forty years of age, who died in his wards in the Randalls Island Hospital on February 8th. He had obtained from the house-physician the following rather scanty history: The man served in the United States army up to 1876, and considered himself perfectly healthy. There was no history of syphilis or rheumatism. At that time, in consequence of a strain, as he believed, a swelling developed in the region of the left testicle, which has since remained without material change. Why he was discharged from the army was not known. His history since then could not be ascertained except that the disease from which he died had existed for some time. He was admitted into the hospital during the month of December, when there existed general anasarca except the face. There was evident hypertrophy of the heart, and the first sound was prolonged. There was fluid in both pleural cavities. The patient suffered from shortness of breath, and there was also found an oblong swelling over the left testicle. He remained in the hospital for some time and improved under rest and the use of digitalis. His liver was also enlarged, and it was said to have extended at one time as far down as the crest of the ilium. Dr. Van Santvoord saw him for the first time in January, and from that time up to February 7th no special change took place in his condition. Physical examination revealed hypertrophy of the heart, the apex beating in the sixth intercostal space and two inches outside of the nipple, reduplication of the first sound at the apex, and also a reduplication less marked of the second sound, heard at the apex but not at the base. There was, besides, marked pulsation in the epigastrium. There was also evidence of fluid in both pleural cavities, over which, on both sides, there was distinct bronchial breathing, although rather distant, bronchial whisper and diminished vocal resonance. A slight systolic murmur was heard over the apex, but it was not transmitted. The liver projected into the abdomen about two inches below the free border of the ribs. (Edema still existed. Dr. Van Santvoord aspirated the left side of the chest, and removed twenty-three ounces of fluid which was clear serum. The bronchial breathing disappeared. The normal respiratory murmur returned with a certain amount of friction sound. The patient bore the operation well, and he proceeded to aspirate the right side. After having drawn out thirteen ounces of fluid an accident occurred to the apparatus by which air entered the chest. Very soon the patient became distressed, the distress became urgent, and within ten minutes he was expectorating frothy material. There was tympanitic resonance over that side of the chest, and evidently considerable air had entered. An attempt was made to withdraw some of the air from the pleural cavity, but it was unsuccessful. The patient died of exhaustion at the end of twenty-four hours. At the autopsy the only thing noticed concerning the brain was that it was slightly firmer than usual. On puncturing the diaphragm through the abdomen air escaped from the thoracic cavity. The right lung was found collapsed and carnified, but no sign of an external opening into the lung was found. In the left lung there was commencing pneumonia in the lower lobe. The heart was markedly hypertrophied and dilated. The pericardium was markedly thickened, and seemed to be undergoing atheromatous change, especially along the line of the

coronary arteries, which were themselves apparently normal. A similar degeneration was found throughout the endocardium, especially on the right side. The valves were normal. The aorta was extensively atheromatous, with a certain amount of cheesy degeneration in the external coat. There was no aneurismal dilatation. The liver was enlarged and showed marked congestion of the central portion of the lobules. The kidneys were embedded in a mass of fibrous tissue one-third of an inch in thickness and perfectly symmetrical, and separated by a pultaceous cheesy layer. The kidneys were entirely normal. The tumor of the testicle was a cyst containing bloody fluid, the testis itself being not more than one-third the size of the opposite one. Microscopic examination of the muscular fibre of the heart showed no degeneration upon the left side, but exhibited a marked tendency to longitudinal splitting of the muscular fibres. On the right side the muscular fibres were in a condition of not very far advanced fatty degeneration. Why heart-failure should have developed was something not particularly explicable from the external examination.

THE ENTRANCE OF AIR INTO THE PLEURAL CAVITY, AND ITS SIGNIFICANCE.

DR. GERSTER asked what the immediate symptoms were after the entrance of air into the pleural cavity.

DR. VAN SANTVOORD said the patient complained within two or three minutes of great dyspnoea; his respiration became panting, and he passed into a state of semi-collapse with cold sweat, and within ten minutes began to cough, and expectorated a frothy, bloody serum.

DR. GERSTER said he asked the question because he thought the simple fact of air entering the pleural cavity in a healthy individual would not be sufficient to produce death. Doubtless, with the patient's bad general condition and his embarrassed circulation and respiration, this accident was the last straw that crushed the camel. Professor König recently removed an extensive tumor with the entire sternum, and in performing the operation opened both pleural cavities, and also opened the pericardium, and air entered each of these cavities. The patient suffered no marked inconvenience, and survived the operation, and made a good recovery.

DR. WATSON referred to a case in which air entered the pleural cavity after an operation for necrosis of the rib, and the patient died within forty-eight hours.

DR. GERSTER referred to the fact that of late years when the pleural cavity becomes filled with pus, an opening is frequently made for the purpose of evacuating it, and immediate bad consequences following the entrance of air rarely take place.

DR. VAN SANTVOORD remarked that in these cases very frequently the empyema is encapsulated.

DR. PUTNAM-JACOBI suggested that the explanation might be in the fact that the lung, in old cases of empyema, has been compressed for a considerable time, and that the shock, which is liable to occur when a comparatively healthy lung is involved by the entrance of air, is avoided.

DR. VAN SANTVOORD thought that the condition of the heart probably explained why death occurred so rapidly from collapse of one lung.

DR. J. LEWIS SMITH remarked that if the pleura is healthy, the admission of a moderate quantity of air did no special harm. In a number of cases in which he had performed paracentesis in children he had known air to enter the pleural cavity, but he had not known that it had produced any ill-effect; but, in one instance, a sharp-pointed needle was used, and the lung was penetrated in three places, and he had reason to think that air escaped from the lung into the pleural cavity.

ENDOCARDITIS—EMBOLIC PNEUMONIA.

DR. PUTNAM-JACOBI presented specimens removed from the body of a child thirteen years of age, who was seen in the out-door practice of the New York Infirmary. She saw it only once during life, and that on the twentieth

day of its sickness. The history was that it had had a febrile attack, which for the first five or six days was markedly intermittent in character, but during the last ten days had been continuous. It was, however, difficult to decide whether the intermittent temperature, varying from 105.5°F. to even sub-normal, 97.5°F. , was due to the type of the disease or to the antipyretic doses of quinine which were administered, and this circumstance contributed to embarrass the diagnosis. The child had had diarrhoea; there was some tympanites, and a moderate amount of hyperæsthesia over the entire abdomen. On the first day it was found that the heart was somewhat hypertrophied. A friction-sound had been heard during twenty-four hours over the left part of the pericardium, but not over the base. On the sixteenth day of the child's sickness a friction-sound was heard over the base of the left lung, which was followed by a certain amount of bronchial breathing in the same region. There was pain over the pericardium, and wandering pains through the limbs, which were readily relieved by the application of chloroform liniment. The temperature was 102°F. , the pulse 120, and the respiration 40. There was flapping of the nostrils, and when the patient sat up in bed she was extremely pale, although there was no lividity. There was no effusion into the pericardium on that day, the friction-sound had entirely disappeared, and only a systolic murmur at the apex could be recognized. There was no positive evidence of fluid in the pleural cavity. At the base of the left lung bronchial breathing could be heard mingled with some râles, and accompanied by dulness, but there was no bronchophony, and vocal resonance was not diminished. Examination of the right lung gave negative results; the abdominal hyperæsthesia continued, and also the diarrhoea. The pains in the limbs had subsided. The child had had an attack of rheumatism one year previous to present illness. The diagnosis was placed between a continued fever complicated with pneumonia, or a visceral rheumatism; *i.e.*, a rheumatism with very slight articular manifestations, but with acute endocarditis and pleuropneumonia. The diagnosis between these two conditions was rendered the more difficult by the enlargement of the liver and spleen. Twelve to fifteen hours after the examination the respiration rose to sixty, remaining so three days, but the condition of the child otherwise was not apparently changed until the end of the third day, when she sank into a comatose condition, and died a few hours later.

At the autopsy the pericardium was found to contain considerable citron-colored fluid. There was also fluid in both pleural cavities. Whether the fluid had been present in the left pleura at the time Dr. Putnam-Jacobi saw the patient, she was unable, for reasons stated, to decide. It certainly was not in the right. Notwithstanding the effusion into the pericardium, its internal surface presented no fibrinous exudation, was perfectly smooth, though somewhat injected. The external surface of the pericardium was covered with fibrinous material, in some places very thick. It adhered to the left pleura. At the base of the left lung, and at the extreme tip of the right lung, recent plastic exudation was found. The left lung was much compressed. In addition, over the lower third of the left lung, were found nodules of lobular pneumonia, which in places projected above the surface, were distinctly circumscribed, and were surrounded by zones of congestion. The right lung, with the exception of the extreme tip referred to, was healthy. The heart showed evidence of endocarditis in both ventricles, but it was difficult to distinguish how far it might be recent, and how far it might date from the rheumatic attack which had occurred the year previously. The mitral valves were very much thickened, and were insufficient, as shown by the water test. The tricuspid valves showed patches of recent injection, were very much thickened, and were covered with apparently recent deposits of fibrin. The liver was very much increased in size, but

otherwise appeared normal. The spleen was very large and soft, and looked very much like the spleen of typhoid fever. The intestines were examined carefully and with negative results. The kidneys were very large, the cortical substance was rather pale, but they had not been examined microscopically. The examination of the urine, during life, had been negative as to albumen. The march of the disease seemed to have been as follows: from either a fresh or from an old attack of endocarditis, particles of fibrin had been separated from the tricuspid valve, and passed into the lungs and set up an embolic pneumonia, which had been followed by secondary pleurisy. The external pericarditis was secondary to the pleurisy, and not, therefore, the direct manifestation of the rheumatic attack. The question why the liver and spleen should be so enlarged was not explained. The fact suggested a septic endocarditis, rather than rheumatic.

DR. VAN SANTVOORD remarked that the transmission of vocal fremitus through fluid in adults was not very exceptional, and therefore its presence could not be absolutely relied on to exclude pleurisy.

DR. PUTNAM-JACOBI remarked that this occurred much more frequently in children.

DR. J. LEWIS SMITH asked if it was not rare to find the lesions of endocarditis in the right ventricle.

DR. JACOBI replied that in this case lesions certainly did exist on the tricuspid valve, as well as on the mitral. She further remarked that if it had been positively decided in such a case that the endocarditis was due to rheumatism, it would be interesting to know whether treatment by salicylic acid would be likely to have exercised any special effect in preventing the effusion into the pericardium by means of its supposed action on the rheumatic materies morbi in the blood. Sibson, in "Reynolds' System of Medicine," attributed efficacy to the use of salicylic acid in the treatment of rheumatic heart disease. The patient in question was treated by stimulants internally and poultices over the pericardium.

TUBERCULAR LARYNGITIS—THE VALUE OF TRACHEOTOMY.

DR. BEVERLEY ROBINSON presented a specimen accompanied by the following history, furnished by Dr. Devlin, Senior Assistant at St. Luke's Hospital: Rachel B—, forty-seven years of age, married, and a native of the United States, was admitted October 25, 1882. There was no specific history, nor distinct evidence of hereditary tendency to phthisis. The patient began to lose flesh and strength about five years ago, but definite symptoms did not appear until three years ago when she had an attack of acute laryngitis accompanied by severe dyspnoea. Since then she has been subject to frequent attacks of laryngeal obstruction brought on by slight exposures to cold. Two years ago she became completely and permanently aphonic. There was no history of cough previous to the laryngeal symptoms. During the last six months paroxysms of dyspnoea have been frequent and very severe. Two months ago it was noticed that the dyspnoea was constant. There was no pain nor dysphagia. On admission she was weak, emaciated, had a cough with marked dyspnoea and laryngeal stridor, and was completely aphonic. The urine had a specific gravity of 1.022, and acid; otherwise negative. Physical examination of the chest revealed consolidation at both apices, particularly the left. Wheezing sounds were heard all over the chest.

November 1st.—Dr. Robinson examined the larynx, and found the epiglottis normal, the arytenoids and commissure thickened. In attempts at phonation an oval chink remained. There was marked inspiratory stridor, also heard during expiration slightly. The ventricular bands were very much thickened. The vocal cords were not satisfactorily abducted. The conclusion was reached that it was not a case of phthisical laryngitis. There was circumscribed dulness under the left clavicle, no dulness under the right, outside of this there was hyper-resonance. There was prolonged inspiration and expira-

tion on both sides. The heart-sounds were feeble but normal. Diagnosis, chronic bronchitis and emphysema, chronic laryngitis.

On November 2d the patient was examined by Dr. A. H. Smith, who diagnosticated tubercular laryngitis.

On November 10th the patient was examined by Dr. McBurney, who diagnosticated tubercular laryngitis.

On November 13th it was recorded that the patient had had several severe paroxysms of dyspnoea during the night.

On November 17th the dyspnoea had become quite urgent, and the patient's consent to tracheotomy was obtained. The operation was performed by the house physician, Dr. Charles Remsen, in the presence of Dr. Robinson, and the patient made a good recovery. For several days she was nourished by nutritive enemata. The patient breathed freely through the tracheal tube, the lower angle of the wound failed to unite, and ultimately, despite careful iodoform dressing, it burrowed downward to the sternal notch. During the entire time the patient was in the hospital there had been an evening rise of temperature varying from one to three degrees above the morning temperature, which was always above the normal. No change in the temperature curve was produced by the operation.

On November 25th the patient was examined by Dr. Leaming, who diagnosed fibroid phthisis with thickened pleura, especially over the upper lobes of both lungs.

On December 12th laryngeal examination showed the arytenoids not so inflamed as formerly, normal epiglottis, papillary condition of the inter-arytenoid commissure, and that the vocal cords did not separate well. Diarrhoea developed, which was diminished but not checked by medication. Dr. Lefferts examined the patient, and diagnosed tubercular laryngitis.

On January 10, 1883, the patient died quietly.

At the autopsy, made by Dr. Ferguson, the right lung was found bound down to the thoracic wall by adhesions over the upper lobe in the axillary line and posteriorly. The upper lobe was honeycombed with cavities, varying in size from that of a pin's head to a horse-chestnut. These cavities were surrounded by bands of connective tissue containing tubercles. The lower and middle lobes were congested and oedematous. Along the free border the lung was emphysematous. The left lung was firmly bound to the chest-wall by adhesions. In the upper lobe there were two large cavities, one as large as an English walnut, the other the size of a hen's egg, which communicated with each other, and contained cheesy pus. In the lower lobe were many miliary tubercles and circumscribed masses, yellowish in color and cheesy in character. Many of the bronchial tubes were thickened, and all the cavities communicated with bronchi. The small intestines contained ulcers which involved the mucous membrane, and in the peritoneum opposite were a large number of miliary tubercles. There was extensive ulceration in the cæcum and the ascending colon. The right ovary was the seat of cystic degeneration, the left ovary was atrophied. The other organs presented no noticeable gross appearances.

Larynx: There is an oval opening in the anterior wall of the trachea, median line, dividing the cricoid cartilage, the first ring of the trachea, and the intervening tissues. This opening admits a cylinder $\frac{3}{16}$ inch, in diameter. There are two small, irregular, superficial ulcers, one on either side of the median line, just external to the projections caused by the cartilages of Wrisburg and Santorini. The tissues in the neighborhood of these ulcers are oedematous. There is extensive and deep ulceration of the tissues covering the vocal cords. The arytenoid cartilages are exposed, their only point of attachment being that of the anterior processes to the true vocal cords. The left arytenoid cartilage is much smaller than the right. Examination with the microscope of sections from the neighborhood of the ulceration over the left false vocal cord, shows miliary tubercles, at the periphery

of which are large numbers of small round cells, small spindle-cells, and many giant-cells; their centres are granular. Sections from the lungs show large numbers of miliary tubercles with giant-cells at their periphery and in the tissues of the lung between the tubercles. There is increase in the fibrous tissue in their neighborhood, and similar round- and spindle-shaped cells to those described in the examination of larynx.

There is slight increase in the connective tissue of the kidney. The vessels are slightly thickened. The epithelium lining the straight tubules in places is pigmented.

There is dilatation of the radicals of the hepatic vein, and atrophy and pigment of the hepatic cells surrounding them, there is some fat in the periphery of the ascini. There are a few miliary tubercles in the liver.

Dr. Robinson remarked that he believed tubercular disease occurred relatively less frequently in this country than abroad; certainly in children. Further, it had been stated that laryngeal phthisis had been cured, but he believed that if any cases of so-called laryngeal phthisis had been cured, they were not true laryngeal phthisis. He thought that a positive opinion could not be formed safely concerning the nature of the disease affecting the larynx previous to post-mortem examination. These facts he thought should encourage the persistent use of local applications, for it is probable that the disease may be cured. Too much importance must not be attributed to mere ocular inspection with the laryngoscope. Concerning tracheotomy he regarded it as erroneous to state that the operation is objectionable, because patients suffer from the presence of the tube; for, in the great majority of cases the patients are benefited by the operation, and certainly it is an advantage rather than a disadvantage from the point of view of individual comfort. He also believed that the introduction of the tube was positively beneficial, because rest is thus afforded to the larynx, one of the most important means for effecting a cure, and that tracheotomy should be performed, if done at all, at a less advanced period than it is usually adopted.

GENERAL TUBERCULOSIS IN A CHILD.

DR. H. D. CHAPIN presented specimens of tuberculosis occurring in a child thirteen months old. It came into his service at the Out-door Department of Bellevue Hospital, November 4th, when the mother stated that the child had suffered since November 1st from vomiting and fever, and had had a slight cough for a week. The temperature was 103° F., and the pulse 150. The pupils were normal. He made a careful physical examination, and was unable to find any evidence of disease of the respiratory organs. The child lay in a kind of stupor. He examined it from time to time, suspecting bronchopneumonia, but it was impossible to diagnosticate it from physical signs. The temperature varied from 100° to 102° F. The child, under the use of cod-liver oil and iron, improved. It was then taken with inflammation and suppuration of the cervical glands, but the child recovered from this, and by December seemed to have made a complete recovery. It continued to improve until February 1, 1883, when the mother returned with it, saying that the child had been taken with vomiting and great restlessness, uttered sharp cries, and bored its head into the pillow. The pupils were normal, and also the temperature. Dr. Chapin again examined the lungs and found nothing. On February 9th the child was seized with convulsions of the left side of the body. There was internal strabismus of the right eye. The patient went on from day to day, and finally died in a convulsion. At the *autopsy* there were found tubercles in the lungs, in the spleen, and in the bronchial glands, which were also large and cheesy. There was a large cheesy nodule of the size of a walnut at the base of the lower lobe of the right lung. The brain was soft, and the ventricles were enormously distended with serum. Very minute

tubercles were found along the fissure of Sylvius. The other organs were normal.

DR. J. LEWIS SMITH had seen six cases in which cerebral symptoms had been produced by enlarged bronchial glands pressing upon the large veins, and thus interfering with the cerebral circulation to the extent of giving rise to serous transudation into the ventricles, and in which the brain was otherwise normal.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, February 22, 1883.

ALEXANDER S. HUNTER, M.D., CHAIRMAN.

DR. F. A. BURRALL read a paper entitled

A DISEASE IN CHILDREN SOMETIMES MISTAKEN FOR MALARIA.

Children from one to two years old, sometimes older, suddenly or gradually, from their usual health, become indisposed, pale, perhaps faintly yellowish, have a dry and somewhat warmer skin than natural, irritable stomach, constipation, or scanty light-colored stools. This is the milder form which, if not arrested, tends to further development when the skin becomes decidedly yellow and dry, the pulse frequent, and the temperature elevated, with headache more or less severe, grating of the teeth, and perhaps delirium. The appetite is sometimes voracious, sometimes lost. The irritability of the stomach varies from nausea to persistent and sometimes apparently uncontrollable vomiting. Repeated chills usually occur. The urine contains abundance of urates. In some cases sore throat is present.

Among the causes assigned were, improper diet, check of perspiration, undue excitement of the nervous system, such as nervous excitement from over-playing, studying in poorly ventilated school-rooms, etc.

The essential nature of the condition was regarded as "acute blood-poisoning due to defective hepatic secretion." The indication was to promote excretion by the natural channels. Clinical experience had shown that this could be done by giving mercurials. In such cases, therefore, he recommended calomel, one-sixth to one-fourth of a grain every hour, placed on the tongue dry, until four or five doses have been taken or the bowels begin to act.

DR. J. C. PETERS said that he had seen many cases of the class mentioned by Dr. Burrall, and was aware of the good effects produced in them by mercury. Other remedies, however, might answer an equally good, perhaps better purpose, according to the experience, and a favorite combination with him was four parts of the tincture of aloes, United States Pharmacopœia, and one part fluid extract of licorice, and of this give one fourth or one-half or one drachm according to circumstance. Another remedy is the phosphate of soda.

He believed there was a class of mixed cases which did not always yield promptly to quinine, but by a combination with one of the remedies mentioned, the quinia acted more favorably than when given without an adjuvant.

DR. JOEL FOSTER had been familiar with the class of cases alluded to by Dr. Burrall and could corroborate the statement made concerning the good effects produced by calomel.

DR. A. C. POST said that much was heard concerning the frequency of malarial diseases in New York. He, however, had practised in this city for more than fifty years and did not remember that he had ever seen a case of typical fever and ague that had not been traced to exposure beyond the portion of the city where the paving and sewerage had been completed, or else in the country.

DR. HUBBARD referred to cases in which patients, who had never been out of the city, had suffered from true intermittent fever. There were two localities, namely, at the corner of Bedford and Carmine Streets and at the corner of Canal and Hudson Streets, in which such cases occurred not infrequently.

DR. SELL said that mercurials produced only temporary benefit, according to his experience in such cases, but when he had treated them with irosin, euonymin, and bicarbonate of soda combined and triturated into an impalpable powder, the good results obtained had been permanent.

DR. J. LEWIS SMITH mentioned several diseases liable to be mistaken for malarial fever in children, such as meningitis, tuberculosis in the upper part of the lung, typhoid fever, etc., etc.

DR. BEVERLEY LIVINGSTON then read a paper

ON THE VALUE OF BISMUTH IN THE TREATMENT OF ULCERATIVE STOMATITIS AND NOMA.

The communication was essentially a review of the subject, suggested by the paper recently published in THE MEDICAL RECORD by Dr. C. J. Macguire, and was based on the use of the remedy in the Nursery and Child's Hospital by Dr. E. L. Partridge in 1881 and 1882, and his own experience as Visiting Physician in the same institution. Concerning the diagnosis he thought the term noma should be reserved for those cases which end in perforating gangrene of the cheek, and that the differential diagnosis between it and ulcerative stomatitis could be made from the facts: 1, That the ulceration in one (noma) begins upon the cheek and upon the gums in the other; 2, that there is greater induration in noma than in ulcerative stomatitis, and the gangrene is very much more rapid in the progress, etc. Thirty-one cases had occurred in the hospital; twenty-three before bismuth was recommended and eight afterward. In all the cases in which bismuth was used, iron, quinine, and whiskey were given according to indications. The parts were cleansed with carbolic acid solution, cauterized with the solid stick of nitrate of silver and packed with bismuth. Three deaths occurred among the twenty-three patients treated before bismuth was used, and two in the eight cases which occurred afterward. In one case, bismuth failed and alum cured. One case progressed to true noma under the use of bismuth. According to his experience and from the history of the bismuth treatment in this hospital, he had more confidence in the thorough use of the solid stick of nitrate of silver followed by the application of alum, or probably better, alum combined with bismuth, than in bismuth alone, and was forced to the conclusion that bismuth is no more a specific for ulcerative stomatitis and noma than is pilocarpin for diphtheria.

DR. MACGUIRE remarked concerning diagnosis, that many of his cases were seen by other physicians, all of whom corroborated the diagnosis of cancrum oris, and that the cases were published some months after they occurred. The object in publishing them was to elicit a fair test of the remedy. His method of treatment was to clip away all the gangrenous tissue, thoroughly cleanse the tissue with permanganate of potash— $\frac{3}{j}$ to $\frac{3}{iv}$ —once a day, and then pack the ulcer with bismuth, which was applied every three hours. In all his cases there was no loss of teeth, no exfoliation of bone, and no further destruction of soft parts. The general treatment was the same as that used in Dr. Livingston's cases.

The Section then adjourned.

A CHILD BORN WITH TEETH.—Dr. Kochman of Strasburg relates the history of a primipara who gave birth at full term to a healthy child with the two lower internal incisors just beginning to protrude. These were out and well grown at the end of a week.—*Allgemeine Medicin Central Zeitung*.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

A STRIKING ILLUSTRATION OF THE INFLUENCE OF HEREDITY IN THE TRANSMISSION OF INSANITY—THE MOTHER OF THE EXECUTED MURDERER MENESCLOU—THE NEW SCHOOL OF MEDICINE—THE FRENCH OPHTHALMOLOGICAL SOCIETY—AN INTERNATIONAL EXCHANGE OF COLLEGE THESES—THE DISCUSSIONS OF KOCH AND PASTEUR—THE NOMINATION OF DR. RANVIER.

PARIS, February 23, 1883.

A VERY striking illustration of the influence of heredity in the transmission of disease, and particularly that of insanity, has just been witnessed in Paris in the following case. It may be remembered that about two years ago a young lad by the name of Menescloeu was guillotined for the murder of a little girl whom he had cut to pieces after having committed rape on her. Doubts were raised as to his sanity, but the experts who had examined him came to the conclusion that although the young culprit was evidently of weak intellect, yet he was intelligent enough to understand the enormity of his crime and that he was consequently responsible for what he had done. The counsel for the defence, however, insisted on the unsoundness of his mind, and during his confinement in prison he was closely watched, but beyond a little eccentricity of manner and occasional outbursts of passion nothing abnormal was observed in him. At the necropsy several important lesions were found in the brain, which the medical men who examined the body considered sufficient to cause great derangement of his intellectual faculties, and that, therefore, he was not cognizant of what he had done. It was, unfortunately, too late to have made the discovery, and it is no wonder that whenever cases of the kind occur a general outcry is raised against the profession and it is set forth as a good excuse by those who persistently plead for the abolition of capital punishment. I must say that the experts did not come out very brilliantly in this case, and what would tend to disprove their diagnosis is the fact that the mother of Menescloeu, who is forty-five years of age, has just been sent to a lunatic asylum, and it has been ascertained that the father of the latter died a lunatic and a brother of hers committed suicide. She is the subject of monomania, and of that form which the French alienists designate "délire de persecution."

The new School of Medicine, or rather the new addition to the old building, which was commenced about three years ago, seems to be making some advance, though very slowly, toward completion. A good deal of the scaffolding has been removed, and the front of the building presents a monumental aspect, the principal entrance of which is decorated with two allegorical figures—the one representing medicine and the other surgery. To make room for the additional building, several dwelling-houses had to be pulled down. Among them was one which bore the number 30, and which was occupied by the notorious Marat when he was stabbed by Charlotte Corday.

It has been proposed to establish a new school of Military Medicine in one of the larger cities of France, not including Paris, to replace that which the French lost by the annexation of Strasburg to Germany in the last war. The faculties of Montpellier, Bordeaux, and Lyons claimed the favor, but the Minister of War has decided for the last named city as being the most central, and possessing other advantages over the cities named.

A bust of the late Professor Bouillaud has been placed in the hall of the Academy of Sciences. It is now proposed to erect a statue by subscription to his memory, for which purpose a list for subscriptions is open at the

Academy of Medicine, and under the auspices of the President of the Medical Association of the Charente, the birth-place of this illustrious physician.

The Academy of Sciences has awarded the "prix Montyon" to Dr. Maillot for his interesting works on the continued forms of fever as they occur in tropical climates.

A new society, under the name of "Société Française d'Ophthalmologie," has just been formed in Paris, meetings of which are to be held annually, and the society is open to all those who speak the French language. It counts already a goodly number of members, among whom are to be found for the present, Belgians, Swiss, and Spaniards.

According to an agreement entered into between the French faculties and thirty foreign universities a regular exchange of theses and dissertations will be officially effected. The first exchange took place in December last.

You are aware of the discussion that has been carried on for some time between Professor Koch, of Berlin, and M. Pasteur, the eminent French biologist. The various communications made by the latter to the different learned bodies on the subject of microbes and the different kinds of virus, are to be put up in a condensed form for early publication.

Dr. Ranvier, the eminent histologist and professor at the College of France, has been nominated corresponding member of the Academy of Sciences of St. Petersburg.

MEDICAL LATIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: May I ask the privilege of an additional brief space in your valuable journal, for the purpose of replying to the communication of Mr. John A. Armstrong (MEDICAL RECORD, February 3, 1883), containing a criticism of my "rejoinder" (*Ibid.*, December 2, 1882) to his paper on "Medical Latin" (*Ibid.*, November 25, 1882). I am aware that the subject is one almost foreign to the purposes of this journal, and therefore do not intend to encumber your pages with any further communications on this subject.

Leaving aside, for the present, the minor points on which Mr. Armstrong and I differ, I will at once revert to the two main points at issue, namely:

First.—Whether such terms as *Carbonas*, *Sulphas*, etc., should be regarded as masculines or as feminines.

Second.—Whether *Rhus glabrum* or *Rhus glabra* is the correct pharmacopœial title to denote the fruit of the smooth sumach.

Concerning the first point, the reasons which convinced me that those nouns should be masculines—and which convinced, so far as I knew before Mr. Armstrong's communication, all others who had occasion to give an opinion on the subject—were pretty fully published in *New Remedies* (1882, p. 58). They were not quoted here, as I wished to save space, and they will be merely outlined even now, since it may be presumed that those who are sufficiently interested in the argument will consult the article quoted.

Mr. Armstrong, having read the paper, states "that it refutes itself," and "that it presents no arguments," etc. I fail to see, however, how he arrives at this conclusion.

My argument is, in brief, the following: Such modern Latin terms as *Carbonas*, etc., should follow the analogy of true Latin nouns of similar termination, so far as the genius of the language permits.

Now, we find two classes of such nouns (having *-itis* in the genitive¹), namely: first, the large group of nouns

¹ Mr. Armstrong adds a note, on page 139, second column, in which he informs us that "*Genitivus* is formed from *genitum*, supine of *gigno*. The Greek name is γενική πτωσις" (*sic*). This is probably meant as a criticism of my spelling "genitive" in my last paper (where it is once printed "genitive" by oversight). But the form "genitivus" is now preferred by the best authorities (Neue, Kruger, Halm, Keil, etc.), as being authenticated by the best manuscripts, notwithstanding the supine *genitum* and the Greek γενική πτωσις.

in *-tas*, *-tātis*, which denote a quality or property, that is, an abstract idea. These nouns are feminines, without exception, in Latin as well as in the cognate or derivative languages. Since the technical terms *Carbonas*, etc., evidently do not belong to this class, neither having the characteristic secondary noun-suffix (*-tātis*), nor denoting any abstract idea, we must look elsewhere for an analogy.¹

The second group of nouns in *-as*, *-ātis*, are those which were originally adjectives (patronymic, geographical, etc.), and which have a gender corresponding to the idea or noun understood.

Mr. Armstrong does not accept the view that *Carbonas*, etc., should be classed here, because he thinks that these modern terms are pure nouns which have never been used as adjectives, and which do not require a supplementary noun in order to be understood.

Now, I never meant to assert that *we*, who use these terms constantly, are compelled mentally to supply a noun, such as *sal* (salt), in order to understand them. In fact, I consider them to be good substantives, just as Mr. Armstrong does. But the case was different with those who *invented* the terms and introduced them into literature. Chemists had previously been in the habit of denominating salts (among other methods) by such terms as *sal phosphoreus magnesiæ*, *sal acetosus argenti*, etc.² The reformers of nomenclature substituted a single term for the *sal phosphoreus*, namely, *phosphas*, and *acetas* for *sal acetosum*, etc. And they used these new terms as masculines, simply because the idea of *sal* still floated before their minds. Other writers even used those terms as neuters, since they may have been accustomed to use the Latin noun *sal* as neuter.³

While such a process of mental supplementation was quite natural to those who first used these terms, who had been long accustomed to use the older method, this process is not at all necessary nor likely to take place in the minds of those who learn chemical terms in our day. We regard the latter now as true nouns, denoting concrete things, and we require no mental supplement to understand them. This, however, does not invalidate the history of the origin of the terms, nor their claim to be regarded as masculines, since we know precisely how they came to be formed, and since we can readily follow the train of thought of those who designed them.

Mr. Armstrong writes: "The 'translators,' desirous of names as homophonous as possible to the original substantives, had warrant, most assuredly, in the examples of *anas* for *anitis*, and *satis* for *satietas*, in writing *acetas* or *acetitas*."⁴

Now, I venture to say that the "translators" (of the London Pharmacopœia, 1809) never thought of those two solitary words, but that they merely followed the usual routine of grammars, or that they struck, for themselves, a mental balance of the Latin nouns in *-as*, *-ātis*

(irrespective whether a *t* precedes this termination or not), and having, as they thought, found an overwhelming majority on the feminine side, selected this gender.

And I further venture to assert that *acetas* does not stand for *acetitas* any more than *sulphas* stands for *sulphitas*, or *nitras* for *nitritas*. *Acetitas*, etc., can only mean "the condition of being an acetate," "the acetate-ship," an abstract idea; its employment to mean a concrete substance would be utterly foreign to the genius of the language.

That the similar terms in *-is*, *-ītis*, must follow the analogy of the terms in *-as*, *-ātis*, requires no argument, because the implied idea in both cases is the same, and there are ample analogies for their use as masculines in Latin.⁵

An additional support for my view (and that of others) of the gender of these technical terms is offered by several modern languages which have adopted them, and in which they are either *masculines* or *neuters*, according to the gender of the word meaning "salt." So in German, where *Salz* is neuter, we say: "Das Sulfat," "Das Nitrat." In French and Italian, where the words for "salt" are masculine, we have: "le sulfate," and "il solfato."⁶

With regard to *Rhus*, I have nothing to add to my argument that the botanical name of the *plant* should denote the *part* of the plant understood in the Pharmacopœia.

So far as relates to the gender of *rhus*, Mr. Armstrong truly says that the authorities differ. There are examples for *rhus* (as tree), both masculine and feminine. Concerning the passage from Celsus, Mr. Armstrong implies that I *prefer* the reading which makes it masculine. But I do not need to prefer any, since the manuscripts and editions, so far as I know, offer no other, and neither the differing genders of *rhus* (as tree), nor the fact that *rhus* (as seed) *does* occur as neuter (besides feminine), can disprove my argument in favor of *Rhus glabra* as pharmacopœial title. Mr. Armstrong wants *Rhus glabrum*, and he wants this translated, not "the glabrous fruit of *Rhus*," but "the fruit of the glabrous *Rhus*." If this translation is admissible, then *malum aureum* might with equal right be translated "the fruit of the golden apple-tree."

As to the declension of *rhus*, I am aware that many forms occur in different authors, and the list given by myself and by Mr. Armstrong could possibly be still further increased.⁷

It is conceded, as I already stated in my last paper, that the Greek *ῥῖος* may be declined either in the second or the third declension. In *Latin*, however, *rhus* is restricted to the third declension. The accusative is either *rhun*, *rhoa*, or *rhum* (occurs only once). *Rhūn* is the Romanized Greek form *ῥῖον* (though it might also be the contracted form of the accusative of the second (attic) Greek declension). Mr. Armstrong finds it singular that I should regard *rhum* as an accusative of the third declension. I have done so and do so still, first, because the other forms of the *regular* Latin second declension (gen. *rhi*, dat. *rho*) are missing, and second, because I regard *rhum* as a Latinized accusative, contracted from *rhū-em*, just as we find the genitive form *rhūis* (see note to my last paper), which is contracted from *rhū-is* (for *rho-is*).⁸

¹ In my paper, in *New Remedies*, I quoted *lis, litis*, as the only true Latin noun in *-is, -ītis*. Mr. Armstrong quotes another *Dis, Ditis*, which I omitted, as it is a contracted form. The adjective *dis* (for *dices*) has no bearing on the argument.

² In Spanish, we have "el sulfato" as masculine, although *sal* is feminine. But the Spanish chemical nomenclature is based on the French.

³ I believe to be correct in assuming that the misplaced or missing accents in some of the Greek forms quoted in Mr. Armstrong's paper, are merely oversights of the proof-reader. But to the same category belongs the *Palladius Martialis* (in my copy it was *Mirt.*), in the note to my last paper, which Mr. Armstrong draws special attention to. I have handled my own copy of *Palladius* often enough to be aware of his name. The mistake arose from a transposed correction made in the preceding line, where the name *Gargilius Martialis* appears.

⁴ I do not regard *rhūis* as the Greek contracted genitive *ῥῖος*, because the contraction in this case is regarded generally as inadmissible. See Kühner, *Ausführliche Gram. d. Griech. Sprache*, I, 349, Anm. 2.

¹ The circumstance that the term *Acetas* apparently belongs to this class does not interfere with the argument, since the *t* (as Mr. Armstrong himself acknowledges) does not belong to the termination.

On the other hand, the noun *acetas*, which Mr. Armstrong draws to the second group in *-as, -ātis* (since he regards the *t* as belonging to the root), really belongs to the first class. The root is *acē* (belonging to Sanskrit *indh*, Greek *ἰδν* (*αἰδν* *αἰδν-ῖος*, etc.), Lat. *acē* (*acē-es, acē-tas* (for *acē-tā*) etc.), and the termination is *-tas, -tātis*. Compare Vanicek, *Griechisch-Lateinisches Etymologisches Wörterbuch*, Leipzig, 1877, I, 85, and the authorities quoted on p. 86.

² Also *sal phosphoreum, sal acetosum*, etc.

³ *Sal* occurs both as masculine and as neuter. See Neue, *Formellehre d. Lat. Sprache*, I, 697-698.

⁴ In my paper, in *New Remedies*, I stated that *anas, anātis* ("old womanhood") formed an apparent exception, inasmuch as it was a *feminine* not ending in *-tas*. My explanation, that it was contracted from a word in *-tas* (just like *satis*), quoted by Mr. Armstrong), is, in my opinion, sufficient to bar its use as an argument against me. I also mentioned, as "the only true Latin noun in *-as, -ātis*," the word *anas* (*anātis*), the duck. Mr. Armstrong remarks to this: "No philologist would so characterize it. It is a metathesis of *ῥῖσσα*; theme *ῥεω*, whence Latin *no*, to swim, etc." In reply to this I can only say that I trust there is no philologist who would assert that the Romans coined the word *anas* after the Greek *ῥῖσσα*, or that they derived the word (and idea) for swimming from the Greeks. There are thousands of good Latin and good Greek words which are derived from a *common form* in the mother-language. There are others again which can be shown to have been borrowed or been transplanted by commercial, military, or migratory expeditions and the like. I consider the etymological connection between *anas, ῥῖσσα, ῥεω*, no (old high German *anut*, Anglo-Saxon *enad*, Luth. *antis*, etc.) as well established, but I also consider the duck (with *Hehn*, *Kulturpflanzen und Hausthiere*, 2te Aufl., Berlin, 1877, p. 323) to be a native of Italy as well as of Greece.

There is, of course, no objection to regard *rhum* as the accusative singular of the second declension. Yet I prefer the former view and think I have sufficient authority for doing so.¹

CHARLES RICE, Ph.D.

NEW YORK, February 25, 1883.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 3, 1883, to March 10, 1883.

BROWN, HARVEY E., Major and Surgeon. To be temporarily assigned to duty at Mount Vernon Barracks, Ala., during the absence on leave of Captain T. A. Cunningham, Assistant Surgeon. S. O. 17, par. 2, Department of the South, March 6, 1883.

CALDWELL, D. G., Captain and Assistant Surgeon. To be relieved from duty at Fort Fred. Steele, Wyo., and will report in person to the Commanding Officer at Fort Laramie, Wyo., for assignment to duty at that post. S. O. 23, Department of the Platte, February 27, 1883.

HOPKINS, WM. E., First Lieutenant and Assistant Surgeon. The leave of absence granted December 28, 1882, is extended two months. S. O. 56, par. 5, A. G. O., March 9, 1883.

PAULDING, H. O., Captain and Assistant Surgeon. The leave of absence granted in S. O. 11, Department of the Platte, January 27, 1883, is extended twenty days. S. O. 23, Military Division of the Missouri, March 2, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 10, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
March 3, 1883	0	8	69	6	100	49	3	0
March 10, 1883	0	13	108	4	109	40	0	0

A DINNER TO OLIVER WENDELL HOLMES.—As an expression of appreciation of the honor Dr. Oliver Wendell Holmes has won for American medical and general literature during the past forty years, a complimentary dinner is to be given to him at Delmonico's, April 12th, by the medical profession of this city.

Dr. T. Gaillard Thomas is chairman of a committee of thirty representative men of all the different interests and sections of the profession, which insures a perfect success, not only as to numbers, but as regards the entertainment in all respects, as the gentlemen who are to respond to the toasts are the most distinguished in their respective professions for their eloquence and wit on such public occasions. The tickets for the dinner are to

be ten dollars, and those wishing to secure them should apply to either of the following gentlemen: Drs. E. G. Loring, F. R. Sturgis, John G. Curtis, George G. Wheelock, Paul F. Mundé, the committee who have this in charge. Tickets cannot be obtained after April 1st, and to prevent disappointment it is absolutely necessary to apply as early as possible, as the number who wish to be at the dinner is likely to exceed the capacity of the dining-hall.

NEW PORTABLE TESTS FOR ALBUMEN.—Dr. Pavy has devised some ferrocyanic pellets, which are portable and keep well, and which furnish, it is claimed, a very delicate test for albumen.

Dr. G. Oliver has prepared test-papers saturated with various reagents, more sensitive than heat or nitric acid to albumen, extremely portable, but little liable to deterioration from exposure to the air, and quite devoid of the corrosiveness which interferes with the portability of nitric acid. The papers were saturated with potassium-mercuric iodide, potassium ferrocyanide, potassium-mercurio-iodo-cyanide, sodium tungstate, and picric acid; and all gave sensitive reactions with slightly albuminous urine.

The above preparations seem to be useful, but we fear that heat and nitric acid will still remain popular, because these latter furnish some idea of quantitative change.

DEATH OF PROFESSOR SIGMUND.—Professor Sigmund, of Padua, recently died at the age of seventy-three. For twenty-four years he conducted the clinic for syphilis at Vienna, being associated with Hebra. He is best remembered, perhaps, on account of his having associated a particular gland in the arm (known as Sigmund's gland) with the diagnosis of syphilis.

GRAND TRUNK RAILROAD SCHEDULE OF SURGICAL CHARGES.—Our Canadian brethren are justly exercised over the schedule of charges drawn up by the Grand Trunk Railroad for its surgeons. The fees for a day visit are \$1; night visit, \$2; office consultation, 50 cents; surgical dressing, \$1; amputation of foot, \$20; leg, \$25; thigh, \$50. It seems a good deal like robbery when a rich corporation refuses to pay a poor doctor but \$20 for, we will say, a Syme's operation with subsequent treatment.

THE ST. JOSEPH MEDICAL HERALD is a new medical monthly. It is unusually well edited.

THE LATE DR. ALEXANDER MING FISHER.—At a meeting of the Medical Staff of the Northern Dispensary, held February 26, 1883, the following action was taken:

Whereas, We have with deep feelings of regret learned of the death of Dr. Alexander Ming Fisher, in Cologne, Germany, on the 12th inst.; therefore,

Resolved, That in the death of Dr. Fisher we feel that the dispensary has lost an efficient physician, the members of the staff a valued friend and courteous co-worker, and the community an esteemed and worthy gentleman.

Resolved, That these resolutions be published in THE MEDICAL RECORD, and that a copy of them be transmitted to the family of the deceased.

ISAIAH F. PRAY, Chairman.

NELSON H. HENRY, Secretary.

SUIT AGAINST A MEDICAL COLLEGE.—An important decision was rendered recently against the United States Medical College, a so-called eclectic institution of this city. In April last the Attorney-General began a suit in the Supreme Court to set aside its incorporation. The officers of the college demurred to the complaint, but before argument could be heard the Legislature amended the general act of 1848 by providing that scientific and literary colleges and universities that had reported their organizations to the Regents of the State University within two years prior to the passage of the amendment

¹ There are analogies for the above, for instance, among Greek words in *ys*, such as *Ity*s (gen. *Ityas*), which has in the acc. either *Ity*n (the regular Greek form, Verg. Aen., 9, 574; Ovid. Metam., 6, 652) or *Ity*m (Prop. 4 (3), 10, 10). *Haly*n (Cic. de divin. 2, 56, 115; Liv., 38, 16, 13), or *Haly*m (Verg. Aen., 9, 765). The forms *rhu*-m, *Ity*-m, *Haly*-m, etc., might also be supposed to be formed without the binding vowel *e*, and subsequent contraction; I think, however, that a contraction took place, for I find the open form *Imity-em* (Plin. hist. nat., 6, 7, 7). "*Rhum*" being the only instance occurring where an accusative in *um* was possible, of course no further examples of this form can be quoted.

should be declared legally incorporated. The demurrer was then withdrawn and an answer was put in asserting that the United States Medical College had been legalized. Judge Van Vorst decided on March 7th, in Supreme Court, Special Term, that the amendment did not legalize the college, for the reason that it had been decided by a General Term of the Supreme Court that words in an amendment passed in 1870 to the act of 1848, similar to those in the amendment of 1882, which define the institutions to be legalized by it, do not include medical colleges in their meaning.

THE NEW YORK MICROSCOPICAL SOCIETY held its annual meeting in this city on March 8th. The President, Mr. Benjamin Braham, delivered an address. An exhibition of microscopical objects was given by the members, fifty or sixty microscopes being used. The circulation in fish and frogs was shown and the bacillus tuberculosis. The exhibition was highly creditable to the Society.

THE OFFICE OF STATE COMMISSIONER IN LUNACY was abolished in the Appropriation Bill as passed by the New York State Legislature. It was stated that the State Board of Charities could do the work as well. We never had great confidence in the utility of a single lunacy commissioner, but to abolish the office without substituting something in its place is a step backward.

ANOTHER CREMATION.—The late Mr. Henry Seybert, of Philadelphia, was cremated at Washington, Pa., on March 7th. This is the seventeenth cremation at this place. Mr. Seybert left \$60,000 to the University of Pennsylvania. It is stipulated that an impartial investigation of modern spiritualism be made. The sum of \$1,000 or \$5,000 was given to nearly every charitable or educational institution in the city.

APPROPRIATIONS FOR STATE MEDICAL CHARITIES.—The Supply Bill was reported to the New York Legislature on March 7th. It includes the following items: New York Idiot Asylum, \$10,000; Binghamton Asylum, \$36,230; Auburn Insane Asylum, \$6,500; Seamen's Retreat, \$1,244.35; Willard Asylum, \$3,000; Buffalo Insane Asylum, \$18,300; State Homeopathic Asylum, \$12,200; Commissioners in Lunacy, \$300; Disbursing State school tax, \$25,000; American Museum of Natural History, New York, for departmental instruction to school-teachers, \$12,000; Quarantine Commissioners, \$1,500; State Board of Health to prevent adulteration and sale of food and drugs, \$10,000; State Board of Health to enforce law regulating sale of illuminating oils, \$3,500; State Board of Audit, \$18,777.71.

ALCOHOL AND THE STOMACH DIGESTION.—Man is a carnivorous animal, according to Lewin, and should eat flesh as much as possible. He should not drink alcohol, since that hinders flesh digestion. Dujardin-Beaumetz, however, takes the opposite view, and thinks that wine may be taken with meat, since, as Richet shows, it increases the acidity of the gastric juice. Vulpian and Mourrut found that alcohol in excess hindered digestion. Levin and Petit de Sèmerie found the same as a result of experiments on dogs. Three dogs were fed with 200 grammes of flesh: dogs 1 and 2 received also 25 grammes of brandy; dog 3 received 75 grammes of the same. In No. 3 there was no digestion; in No. 1 and 2 it was unimpaired. Fleischer has obtained similar results.

THE TREATMENT OF SCALP WOUNDS.—Dr. W. S. Parker, of Piqua, Ohio, writes: "An article on scalp wounds in the last number (February 24th) of THE RECORD, prompts me to communicate a simple device I have used for the last twenty years in such cases. After cleansing the wound thoroughly, all hemorrhage being suppressed, bathe the parts freely with balsam Pern, a time-honored, but none the less valuable antiseptic. Then, presupposing its existence, comb up along the edges of the wound, and exactly opposite, for the space of say half

an inch, the hair, which twist into a thread and tie with a *single* turn, drawing the edges of the wound gently but firmly together. Having previously laid a well waxed ligature beneath the hair and parallel with the wound, tie with the thread the single loop of hair, employing a surgeon's knot. Repeat the process, *i.e.*, another single loop and surgeon's knot, and you have a fixed dressing. The coaptation of the flaps is necessarily perfect. I have not hesitated to use sutures when necessary, owing to the absence of hair or its being too short, or from loss of tissue, and in my entire experience have had but one case of erysipelas following their use, which seems to bear out Professor Gross' teaching of the harmlessness of sutures in the scalp."

CHLORAL HYDRATE AND BROMIDE OF POTASSIUM IN DELIRIUM TREMENS.—Dr. W. Washburn, of this city, mentions a plan of administration by which these remedies have proven effectual, when other means as well as large doses of chloral had signally failed. He advises, first, that the bowels be thoroughly moved with croton oil, following which, from a solution of chloral hydrate, gr. ij., ʒj., and potassium bromide, gr. v., ʒj., he administers four drachms as the first dose. At the expiration of twenty minutes or half an hour, a second dose of one drachm is given, and repeated every fifteen minutes until sleep is produced. From this method of administration it is claimed that a quiet and refreshing sleep is induced usually after the second dose, and, in his experience, nothing has given such speedy and excellent results in the treatment of these cases.

THE TONGUE UNDER THE MICROSCOPE.—Dr. G. P. Hachenberg, of Austin, Texas, has been making a series of microscopical examinations of the tongue, with a view to establishing the diagnostic value of its appearance, not only in disease of the liver and alimentary canal, but also in lesions of the respiratory organs, in the cachexiæ, etc. To this end he invites the attention and co-operation of the profession, and proposes to utilize the material received in a treatise on this subject. All reports will be duly accredited by him.

ANATOMICAL TECHNOLOGY.—In the review of this work, published in THE RECORD of February 10th, the word "dorsiverting" is quoted when the text says "ventrigructing," and the author writes us that it should be "dorsiverting."

IODINE AND BLISTERS IN TABES MESENTERICA.—In tabes mesenterica, Dr. Bouchut, of the Children's Hospital, recommends the application of blisters, or the tincture of iodine, upon the abdomen. If ascites be present, tapping should be employed without hesitation. The *régime* to be followed should be very severe—beef-tea, eggs, raw milk, and claret. If diarrhœa be present, enemas of borax, one drachm each time, should be given, and three or four teaspoonfuls of glycerine in the day, by the mouth. Bismuth, or phosphate of lime, would be very useful. Your correspondent tried this treatment in an apparently hopeless case, and a rapid recovery ensued. The disease was far advanced, and the child was abandoned by its ordinary medical attendant.—*Medical Press and Circular*.

THE MINNESOTA COLLEGE HOSPITAL held its Annual Commencement in Minneapolis March 1, 1883.

A BILL TO REGULATE THE PRACTICE OF MEDICINE in Minnesota has been introduced into the State Legislature. The *Northwestern Lancet* approves the bill in the main, and urges its passage.

THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NASHVILLE held its annual Commencement last week, graduating a class of 125.

BEQUESTS TO LONDON HOSPITALS.—Seven London hospitals have recently received bequests of \$25,000 each from Mr. George Tierney, recently deceased.

Original Lectures.

ON THE RELATIONS OF MICRO-ORGANISMS TO DIS- EASE.

THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE
ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSI-
CIANS AND SURGEONS, NEW YORK.

By WILLIAM T. BELFIELD, M.D.,

LECTURER ON PATHOLOGY, AND ON GENITO-URINARY DISEASES (POST-GRADUATE
COURSE), RUSH MEDICAL COLLEGE, CHICAGO.

LECTURE IV.

IN this discussion I have referred to various bacteria as distinguished into species by essential differences of form and function. In these latter days it has become fashionable to speak of these minute organisms as transient modifications, due to incidents of their environment, of one and the same organism. Nägeli, indeed, would include not only bacteria, but also some of the higher fungi in this hypothesis. As this seems as yet a speculation, based not so much upon direct demonstration, as upon deductions, it will not require discussion here.

An essential element of this theory, however, the so-called accommodative cultivation of bacteria, seems to be supported by certain experimental evidence. This assumes that the physiological characteristics may be modified by contact with unusual influences—by a change of environment, in other words—as to render the descendants of a given bacterium which is capable of successful contest with the living animal tissues impotent to maintain such combat; and conversely to confer upon a previously harmless bacterial species the power to invade and destroy a living animal. This hypothesis is so fascinating, the solution of many difficult problems is rendered thereby so simple, the reconciliation of conflicting observations and opinions becomes so easy, that every man becomes at once his own bacteriologist. Diphtheria, on this hypothesis, is not due to a specific bacterium, but to some of those usually guileless organisms which ordinarily inhabit the healthy throat, incapable of harm; but which, excited into unusual and perverse activity by unknown influences of atmosphere, etc., invade the body with disastrous results. The application of this assumed principle is evidently limited only by the fancy and ingenuity of the individual; we have been already amply entertained by theories ascribing typhoid fever to the hypothetical tonic influence of sewer-gas upon the bacteria inhabiting the alimentary canal, etc.

The evidence in support of this hypothesis consists of deductions by analogy and of experimental observations. Since the life of an organism is the resultant of many forces, it is *a priori* evident that a modification of one or more of these forces may be followed by a change of the resultant life. In the higher plants and animals we have abundant evidence to this effect; the domestic pigeon and the dahlia are examples rendered familiar to us by Darwin. Such modifications, it is true, require time; but in biology time is measured by generations, not by years; and since from one bacterium a second may be produced in thirty to sixty minutes, it is evident that a day may induce in these organisms the effects of a thou-

sand years in man. The evidence by analogy with higher organisms supports then the theory in question.

This same principle—modification of function by changes of environment—which Grawitz and Buchner had vainly attempted to demonstrate, seems to have been demonstrated by Pasteur in his studies upon protective vaccination. He asserts that the microbes which he regards as the morbid agents in chicken-cholera can be deprived of their virulence by successive cultures in contact with air; so that a given quantity of such culture fluid causes effects far less severe than the same quantity before such modification. Pasteur subsequently applied the same principle to the mitigation of anthrax virus; indeed the list has been still further extended by himself and others. Since in all these cases the same general principle is illustrated, it will suffice for our present purpose to consider the mitigation of anthrax virus for the preventive vaccination of sheep.

Pasteur's theory is this: the anthrax rods, as found in the blood of an animal dead of the disease, when placed in a suitable liquid maintained at a temperature of 42–43° C. grow as usual into threads, but do not produce spores. After a certain time their vitality is lost; when transferred to another flask, kept under the same conditions, they do not grow nor reproduce. But at any time previous to this final extinction of vitality, the bacilli still exhibit life, though their ability to invade a living animal, *i.e.*, their malignancy, is diminished. There occurs, indeed, a gradual *diminuendo* of malignancy, their morbid effect upon an animal decreasing with the prolongation of their exposure to these conditions, high temperature and exclusion of oxygen, until finally both life and malignancy are extinguished. Pasteur found that after eight days the bacilli had lost their fatal power to destroy rabbits, guinea-pigs, and sheep, though these animals are peculiarly susceptible to this virus. He claims that he has thus mitigated the virulence of these bacteria, has induced a modification of function.

As to the accuracy of Pasteur's observation in this case there can be no doubt; the vaccination of thousands of animals has already proven that the mortality induced by such anthrax cultures is much less than that following the usual inoculations with fresh virus. But his explanation, that the decrease of malignancy is due to modification of physiological function, is a by no means necessary conclusion, since precisely the same results can be and have been secured, under circumstances which preclude the possibility of a transmissible physiological modification.

First among these methods is simple dilution. It has been long since and often demonstrated that the effect induced by the incorporation of these virulent organisms into an animal depends, *ceteris paribus*, upon the number introduced. Chauveau found that sheep which had survived injections of fifty to six hundred anthrax bacilli died after subsequent injections of one thousand bacilli each. Oemler had previously made analogous observations upon horses; Löffler upon rats; it is indeed an accepted principle that the effect of inoculation increases with the number of injected bacilli. The somewhat general impression that quantity exerts no influence upon the result, except as to time, may be true when the effect is manifested upon an inert, unorganized mass, but not in the case of a living animal.

Diminution of malignancy can be secured in other ways also, which seem to accomplish practically the same result, dilution of the virus. Nocard and Mollereau found

that anthrax virus is attenuated by simply mixing it with twice its volume of oxygenated water under pressure. Four hours' contact produces Pasteur's premier vaccin (for the guinea-pig), ninety minutes' exposure the second. Chauveau makes the premier vaccin by exposing anthrax blood to a temperature of 50° C. for fifteen minutes; and the second vaccin by the same exposure for nine to ten minutes. Since oxygen under pressure, as well as a high temperature, destroys the anthrax bacilli, it would seem that these methods accomplished merely a dilution of the virus by killing a certain number of the contained organisms; for in the brief time required in these experiments a physiological modification seems scarcely possible.

According to a communication presented by Bouley to the French Academy of Medicine, Peuch discovered that the effects of tag-sore virus (variola in sheep) decreased by simple dilution with distilled water.

* In the case of chicken cholera also, the characteristic organisms of which have been "modified" by Pasteur through a long and interesting process, there is reason to suppose that this modification may be simply a dilution. For vaccination against the disease has been successfully practised by simply introducing into the animal a piece of blotting-paper on which the blood of an infected animal has dried. The bacteria in dried anthrax blood die in a few weeks, but those still living at a given moment exhibit their original functions if transferred to a proper soil, and it seems probable that the diminished virulence of dried chicken cholera blood is due to the death of some of the contained organisms rather than to a physiological modification. This belief is strengthened by a letter recently received from Dr. D. E. Salmon, of Ashville, N. C., in which he says: "I have vaccinated fowls experimentally, both by Pasteur's method and by a method of my own. My method is simply inoculation with a very diluted virus; when sufficiently diluted it produces only a very circumscribed, local irritation that does not affect the general health in the least. One or a dozen germs of this fatal disease may be introduced in the tissues and are unable to produce any effect whatever. Twenty, fifty, or a hundred, according to the susceptibility of the fowl, will produce a slight local irritation. Pasteur's method requires five to nine months to attenuate the virus; by mine it is accomplished in as many minutes."

The effect can be secured, therefore, by simple dilution of anthrax or chicken cholera virus, as well as by Pasteur's cultures, and there are other reasons for suspecting that his mysterious method for the mitigation of bacterial virulence is practically a dilution of the culture, or rather, of the contained bacteria. If Pasteur would demonstrate that his tamed bacilli transmit their tameness to subsequent generations, the question would be finally settled; he asserts, indeed, that he has observed such transmission "in a few cultures," but gives no particulars, while the extensive vaccinations already performed on sheep prove that even his first (weak) vaccin sometimes kills an animal. It is but just to state that Koch has recently expressed his conviction that a genuine physiological modification does occur in Pasteur's cultures; whether this conviction is based upon personal observation or not does not appear.¹

Although proper functional activity may doubtless decrease susceptibility to infectious diseases, whether of bacterial or of still unelucidated origin, it is evident in our daily observation that such activity does not necessarily confer immunity. At present but two avenues to such acquisition are known, a natural attack, and the artificial induction of the disease in mitigated form. The immunity secured by one attack of variola, scarlatina, measles, whooping-cough, etc., and by artificial inoculation with variola, as was formerly extensively practised, prompted experimentation in regard to other diseases. In-

oculation of cattle with material from animals dead of infectious pleuro-pneumonia—lung plague—was begun in Holland in 1852, and soon extended to Germany and Russia. In Saxony the mortality, previously twenty-five to thirty per cent. of the herds, became ten, six, two, even one per cent. At the Cape of Good Hope, where seventy to eighty per cent. of the cattle died of this infection, the disease almost vanished after inoculation was extensively practised. The tag-sore of sheep was always robbed of many victims by artificial inoculation. But of the diseases of whose parasitic origin we have conclusive or strong presumptive evidence, every one may occur more than once in the same subject. It is evident therefore, first, that immunity against an infectious disease, in the ordinary sense of the term, implies not necessarily the absence, but merely a relatively slight degree of susceptibility; second, that the question must be studied as to each disease independently of all others.

Although the question of protective vaccination has been experimentally studied as to anthrax, charbon symptomatique, chicken cholera, septicæmia, by Chauveau, Toussaint, Semmer, Colin, and Rosenberger, yet the results are so closely associated with Pasteur's name and with anthrax that I shall omit extended reference to the pioneer workers and works, and consider as the most favorable example, the well-known experimentation in protecting sheep against anthrax by inoculation with the cultivated bacilli. This method of Pasteur, I might say, is the first one which has afforded results at all satisfactory; and the principle differs from that employed in lung-plague, tag-sore, etc., in that the artificially cultivated organisms isolated from the accompanying animal tissues are employed—a new departure therefore.

In considering this subject, with which Koch's name is almost as closely associated as Pasteur's, it is advisable again to remember that this is a question of facts and not of individuals; that to us Gaul and Teuton are alike friends, as we fortunately keep no watch on the Rhine, that neither Pasteur's brilliant work on fermentation, nor Koch's services on anthrax and tuberculosis; neither the unreasoning enthusiasm of the French for Pasteur, nor the intelligent confidence of the Germans in Koch; neither the grandiose egotism and artful dodging of the former, nor the apparent personal rancor of the latter; none of these may obscure our vision in estimating the value of present evidence.

Pasteur's theory may be briefly stated as follows: Since anthrax does not recur in the same individual, immunity against it as against other infectious diseases may be secured by one attack; the same effect may be obtained as in the variola of the human subject, by a harmless inoculation with the specific virus after exposure to unusual influences whereby its effect upon the animal is diminished.

To this theory Koch remarks that although some of the infectious diseases occur in the same animal but once, as a rule, yet no immunity is secured from others by the first attack; and adduces erysipelas, the septic diseases, gonorrhœa, intermittent fever, and recurrent fever, as examples familiar to all; the last-named is especially interesting, because it is invariably associated with a specific bacterial form—the spirochaete of Obermeier—though final proof of the causal relation of the parasite has not yet been furnished. But more than that: Koch points out, by the records of Prussian veterinary surgeons, that anthrax itself not infrequently occurs twice in the same individual; instances Oemler, who experimented on about one hundred animals years before Pasteur began to work upon the subject; and who saw horses, for instance, exhibit all the symptoms of anthrax once, twice, even eight times—at intervals of weeks or months, after inoculation with anthrax material; quotes Jarnowsky, who saw the disease occur among fifty human patients, twice in one at an interval of two years; three times in another at intervals of two and three years. Löffler found that of 52 rats which were inoculated at intervals of some

¹ I have not succeeded in procuring Koch's monograph; the above statement is taken from reviews of it in French and German journals, the *Deutsche Med. Wochenschrift*, and the *Revue Scientifique*, especially.

days or weeks, with the fresh virus, 30 survived the first, 23 the second, 13 the third, 3 the fourth, and 1 the fifth and sixth inoculation. Koch reminds Pasteur, therefore, that even though an animal survive a virulent inoculation he is not thereby secure against subsequent infection with anthrax. Further, Koch calls attention to the fact—proven by himself and others—that immunity against subcutaneous inoculation is not necessarily synonymous with immunity against infection through mucous membranes, especially of the alimentary canal; although Koch admits that as the fact had been proven only for horses, dogs, mice, rats, and rabbits, it might be otherwise with regard to sheep, with which he had not at that time experimented.

Such were the considerations advanced on either side.

Pasteur's theory was soon extensively tested—in Prussia and Hungary the experiment was superintended by an official commission of medical officers of the government. The proceeding has been usually the same. Pasteur vaccinates first with a weak virus, two weeks later with a stronger one, and after two further weeks, the animal is considered protected; and those thus protected, as well as others not vaccinated, are inoculated with material fresh from an animal dead of anthrax. At the end of the experiment in Hungary, fourteen per cent. of the protected animals were dead—mostly in consequence of the second protective vaccination; ninety-four per cent. of the non-vaccinated died. In Prussia the result was more favorable: 3 out of 25 sheep (twelve per cent.) died after the second protective vaccination. After the final inoculation with fresh blood, all of the non-vaccinated, but not one of the vaccinated, died. Pasteur thus demonstrated that sheep at least may acquire increased power of resistance to subcutaneous inoculation with anthrax; but he demonstrated at the same time that his protective vaccination destroyed almost as large a per cent. of animals as usually die from spontaneous infection in the pasture. Since that time Pasteur seems to have employed less virulent material, for according to accounts in French journals the mortality from the protective vaccination has been often only three, two, one, or even less per cent. But as Koch very properly observes, the ability of an animal to withstand a mild inoculation is not the question at issue, for that has been long known; their subsequent power to resist virulent material is the mooted point. The effect of Pasteur's own virus seems by no means uniform, since Duclaux, his assistant, who probably had virus of the proper attenuation, lost 20 out of 80 sheep in one flock during the two weeks after protective vaccination, and 11 out of 60 in another; yet in a third flock of the same race he lost only 1 out of 50. In the session of the Paris Veterinary Society, June 8, 1882, it was announced by Weber that 23 out of 993 sheep (2.3 per cent.) had succumbed to the preventive inoculation; at a later session Mathieu reported 29 deaths among 896 vaccinations (3.2 per cent.). At Salz-dahlum 2 of 82 sheep died of anthrax after the second vaccination; in Kapuwar 5 of 50, and in Packisch (as already stated) 3 out of 25. Oemler lost 26 among 703 (3.7 per cent.). Dr. Klein recently called the attention of the British Government to the fact that Pasteur's vaccine virus was on sale in England; that he (Klein) had found that even the first and weaker virus could kill animals, having himself lost two sheep by such vaccination. Pasteur replies that Klein must have allowed other bacteria to invade the anthrax liquid.

From these accounts it would appear that Pasteur's preventive inoculation is a somewhat perilous performance, since even when performed by his own assistants it has killed 10, 12, even 25 per cent. of the vaccinated animals. Yet Pasteur recently stated that of nearly eighty thousand sheep vaccinated in France during the past year or two, none had died of the preventive inoculation.

And now for the second question: Does Pasteur's vaccination protect the sheep which survive it against anthrax? Against subcutaneous inoculation it certainly

does for some weeks, as demonstrated in Prussia and Hungary; how long this protection endures and—more important still economically—whether it protects against infection through the mouth and alimentary canal, the usual mode of infection in the spontaneous anthrax of the pastures—these questions are not yet decisively answered. Yet we have already some data, collected largely by Pasteur on the one side, and by Koch on the other. Boutet reports that in the department Enre-et-Loire (where anthrax is especially prevalent, according to Pasteur) the general mortality last year was three per cent.; while of 79,392 vaccinated animals only .7 per cent. died; one herd of 2,308 vaccinated sheep lost only 8, less than .4 per cent.; another of 1,659 unvaccinated animals exposed to the same conditions lost 60 (3.6 per cent.). Nocard vaccinated in August, 1881, 380 sheep, reserving 140 for comparison; during the following five months 4 of the former and 15 of the latter died of spontaneous anthrax. According to these reports, therefore, the mortality of the vaccinated is only about one-tenth that of the unvaccinated animals, though it must be remembered that this does not include the mortality from the vaccination itself.

Other results are decidedly less favorable. Of 266 sheep vaccinated in Packisch last spring by Pasteur's assistant, Thuillier, there died between May and November, of spontaneous anthrax, 4; of 243 unvaccinated kept for comparison, 8. Cagny reported to the Paris Veterinary Society the following observation: In 1881, 20 sheep were vaccinated *à la* Pasteur; in February, 1882, 10 more. They belonged to a herd of 250, 2 of which died of spontaneous anthrax in May and June, 1882; it was therefore deemed advisable to revaccinate, which was done in July with Pasteur's stronger virus. Of the 20 animals vaccinated in 1881, none died of this inoculation; but of the 10 vaccinated only five months previously, *nine died*; of 4 non-vaccinated animals inoculated for comparison at the same time, 3 died. Koch vaccinated 8 sheep after Pasteur's method, and then inoculated them with virulent material; one died. The remaining 7 had therefore been inoculated with anthrax three times. Twelve days later material containing anthrax spores was mixed with their food; 2 of the 7 died of anthrax.

A review of the evidence already adduced indicates that although Pasteur's theory has been demolished beyond repair, yet he has established the fact that the susceptibility of sheep to anthrax can be diminished by vaccination with the cultivated bacilli. From the economic standpoint the value of this measure is still debatable, though the aspect of the question has certainly improved since 1881, when the Hungarian medical commission, after inspecting Pasteur's experiment, advised their government not only to withhold its official sanction, but also to forbid all private experimentation. Nocard and Mollereau claim to have secured immunity of guinea-pigs by their method with oxygenated water; Chauveau with heated anthrax blood. If these claims be substantiated we may hope that simple dilution may furnish a virus which shall protect against other diseases as well as against anthrax. At any rate, Pasteur has established a principle, and it is to be hoped will be merely stimulated by the present unsatisfactory results to future and more successful efforts for its application.

Having thus sketched the present state of knowledge as to the agency of micro-organisms in the induction of disease, I may be permitted to consider briefly certain deductions therefrom, collectively known as the germ theory. I would emphasize the remark that the facts already summarized are not to be confounded with the speculations in which it may please one or another of us to indulge. Ocular demonstration removes a chain of events from the realm of speculation to the domain of fact; hence the germ theory has no longer jurisdiction over anthrax at least. A possible future demonstration that small-pox, syphilis, etc., are not caused by micro-organisms would be disastrous to the germ theory, but

could not change the facts already established as to the morbid agency of the bacillus anthracis.

The germ theory supposes, if I understand it aright, that all infectious diseases are caused by the vital activity of parasitic organisms. In support of this theory there is certainly strong presumptive evidence: the stage of incubation; the unlimited reproductive power of the virus; the cyclical course and self-limitation of the disease. The stage of incubation can be explained by the assumption of no unorganized virus; all mere chemical compounds with which we are acquainted, even the ferments ptyalin and pepsin, begin to manifest the characteristic effects as soon as absorption has occurred.

Panum found that even boiled putrid materials, *i.e.*, the products of bacterial activity, though inducing the other features of septicæmia, failed to exhibit this characteristic incubation. By assuming an organism as the infecting agent this phenomenon becomes intelligible: the stage of incubation is then the period during which the induced organisms are multiplying. In this way, too, the various durations of the incubative stage characteristic of the different diseases become intelligible. We cannot conceive that one chemical poison should require two to four days for the manifestation of its constitutional effects, as in scarlet fever, another forty days, as in syphilis; but we know that different micro-organisms multiply with different degrees of rapidity. A micrococcus may produce a second in thirty minutes; the bacillus anthracis may accomplish its entire vital cycle in twenty-four hours; the bacillus tuberculosis seems to require days. The unlimited reproductive power of the virus, characteristic of many infectious diseases, cannot be attributed to an unorganized poison or even organic ferment. A drop of blood from an animal poisoned with opium or strychnine exhibits only the power of the diluted poison. A drop of vaccine lymph, of variolous or gonorrhœal pus induces, in successive generations, unlimited quantities of identical materials. This effect cannot be justly ascribed even to any physiological unorganized ferment—a favorite refuge of those who are determined to deny to bacteria any influence whatever. Ptyalin can, it is true, convert into grape-sugar many times its bulk of starch, and the ptyalin is not thereby diminished in quantity; but it is not increased. No more perfect illustration of this principle can be furnished than an experiment of Rosenberger, which has especial value because this observer would assign to bacteria a subordinate rôle in morbid processes. He found that the boiled blood and tissues of septic animals—proven to contain no living bacteria—induced septicæmia as certainly as the same blood unboiled. He then placed in one of two flasks containing identical culture-liquids a few drops of the boiled blood, and in the other the same quantity of unboiled blood. Two days later every drop out of the latter flask conveyed septic infection, while large quantities from the former induced no reaction; every drop of the septic fluid was swarming with bacteria; in the other flask there were no organisms.

The virus of an infectious disease must then be something capable of reproduction, and this power is the peculiar characteristic of an organism. No unorganized poison, acid, salt, alkaloid, ferment is at present known which is capable of manifesting the phenomena shown by the virus of syphilis, variola, scarlatina, etc.

Turning to diseases whose parasitic origin is already demonstrated, we find all the characteristics of the infectious diseases exquisitely exemplified. Anthrax is marked by a stage of incubation—twelve to seventy hours—during which the bacilli multiply and effect access to the blood; the onset of constitutional disturbance is marked by the presence of numerous bacteria; with the death and disappearance of these, convalescence begins; the disease is eminently communicable by contact and yet may occur also sporadically and epidemically.

And this leads me to mention a fact often urged as an objection to the parasite theory: that many infectious

diseases are intimately associated with climate, soil, and topographical features, indeed indigenous to certain districts. This is, in fact, strongly favorable to the germ theory. Many plants and animals of larger growth have decidedly limited habitats; botanists and zoölogists have long since informed us that this same principle applies to microscopic organisms, including fungi; shall bacteria then, a family of fungi, be exceptions to the general rule? As to anthrax, the case is answered; the disease is endemic in certain districts, that is, the bacilli grow outside of the animal body only in these districts. Koch has recently endeavored to elucidate the reasons for this. He ascertained that the growth of the anthrax bacilli requires moisture and a temperature of 15° C. It is evident, therefore, why anthrax is not endemic in districts whose surface temperature fails to reach this point. Koch further ascertained, from the official reports of Prussian veterinary surgeons, that after the overflow of rivers and lakes an outbreak of anthrax had been frequently observed in cattle pasturing at certain points along the banks. He found by experiment that the bacilli flourish in infusions of various grasses, grains, and vegetables. Hay infusion is usually a poor soil, because of acid reaction; when rendered neutral or slightly alkaline, the bacilli grow in it luxuriantly; but it had been long before stated by German and French observers that the anthrax districts usually had a calcareous soil. Hence he conjectures that in such districts the alkalinity due to the lime may render even hay a soil favorable to the anthrax parasite; that it may usually grow on decaying plants in such districts. That anthrax is especially prevalent in autumn seems to result in part at least from the fact that these bacilli, like many other fungi, grow only on dead plants. It might be interesting to review for comparison with anthrax the facts which establish the association of various infectious diseases—cholera, yellow fever, the malarial fevers, for example—with local influences of soil and temperature; the origin of typhoid fever in particular wells and springs, as has been conclusively established by observations upon the German and Austrian soldiery. Yet such discussion would transcend my time and my province, since I have attempted to portray what has been, not what remains to be accomplished.

Certain popular arguments against the morbid agency of bacteria are worthy of consideration perhaps, though not because of their intrinsic weight. To some it is incredible that bacteria should harm us, since we live in health though surrounded by them—eating, drinking, and breathing them. If it be remembered, however, that the name bacteria is merely a convenience for designating organisms of widely different functions, this argument seems less formidable. On the same principle it might be asserted that all mammalia are harmless because we come into daily contact with sheep, cattle, horses without injury. The diversity in function, food, etc., among the microscopic beings is not less marked than among the larger organisms: there are bacteria, and bacteria. It is surprising that Mr. Cheyne, in his admirable work on antiseptic surgery, falls into a similar error. He admits that bacteria are not infrequently found under Mr. Lister's own dressings; that sometimes the course of the wound appears thereby unaffected, while at other times he thinks he has observed that the wounds heal less kindly. He consoles himself, however, with the reflection that these are "only micrococci." He seems to forget that several species of micrococci are distinguishable in form, size, color, and function from one another and from all others. The fact that certain micrococci found during different diseases are morphologically indistinguishable from others found under Mr. Lister's dressings, does not justify the assumption that all are functionally identical. If Mr. Cheyne were requested to swallow some pills, he would probably inquire as to their contents before complying, and would not be satisfied with the assurance

that they were "only pills." Yet we have every reason for asserting that the minute globules known collectively as micrococci present differences as great as the larger globules designated, for convenience, pills. When we reflect that the active agents in the induction of pyæmia are micrococci; that the organisms found in malignant diphtheria are micrococci, we must protest against Mr. Cheyne's promiscuous ascription of benign qualities to any tribe of bacteria, even if "only micrococci." There are micrococci and micrococci.

Again, it is said, how is it possible for recovery to occur from a disease caused by bacteria? What stops their growth? So far as I am aware, this question has not been decisively answered. Several facts suggest that the products of their own vital activity arrest further development. Analogous facts have been demonstrated: the mucor racemosus ceases to grow in a liquid when the alcohol produced by its own vital action exceeds a certain percentage, though there may still remain fermentable sugar in abundance. During putrefaction there are produced numerous compounds, of which one at least, carbolic acid, arrests, even in small quantities, further development of putrefactive bacteria. Brieger has recently shown that the infectious diseases proven clinically and experimentally to be caused by putrid infection—pyæmia, diphtheria, erysipelas—are distinguished by the excretion in the urine of excessive quantities of carbolic acid; while in other diseases exhibiting equally intense fever and constitutional disturbance—acute rheumatism and variola, for example—the amount of this acid in the urine is normal or subnormal. Hence the conjecture that the bacteria are both bane and antidote. Yet a failure to explain the phenomena satisfactorily does not, of course, impair the stability of the fact. The bacilli of anthrax are observed to become, in the living animal, pale, of uneven outline, incapable of absorbing staining fluids; in short, they are dead. With their death the convalescence of the host begins, as a rule.

It should be remembered that other parasites than bacteria may cause disease, some of them, perhaps, overlooked in the universal hunt after bacteria. Koch calls attention to Woronin's discovery that a disease of cabbages is caused by an amœboid parasite, which enters the root of the plant and becomes almost indistinguishable from the proper vegetable cells; and suggests the possibility that some of the amœboid bodies known as white blood-corpuscles in animals may be intruding organisms, especially since Ehrlich has shown that different leucocytes exhibit various reactions to staining agents. Five years ago it was discovered that a mould-fungus, the actinomyces, induces fatal disease of man and other animals; Wittich found organisms, which he calls spirilla, in the blood of apparently healthy gophers; Koch found numerous organisms (monads) in the blood of five gophers that had died without other discoverable cause. A new filaria has been recently discovered in the human subject by Bastian, and similar discoveries are reported in the camel and the hog.

There is probably no one among us who doubts that the trichina spiralis can and does induce in the human subject a serious, even fatal disease; yet the evidence as yet adduced is merely the association of the worm with the morbid condition, for no one, so far as I am aware, has ever induced the disease by introduction of the isolated worms. Yet the same men who assert the pathogenetic influence of the trichina, contemptuously reject the idea that leprosy, tuberculosis, recurrent fever, and pyæmia are caused by bacteria, although the evidence—constant association of the parasite with the morbid condition, applies to all cases. Indeed, the weight of evidence is decidedly in favor of the bacteria; for the trichina is found not only in the subjects of trichinosis, but also in many individuals who have never been suspected of harboring the worm. It is not extremely seldom that trichinae are found in the bodies of patients who

have died of acute disease, wounds, accidents, etc.; indeed, an examination of several thousand consecutive cadavers in German hospitals, some years ago, revealed trichinae in over two per cent., without regard to the cause of death. It might, therefore be argued that the presence of the worm is a mere accident—an epiphenomenon, observed in healthy as well as in diseased conditions. The bacilli of leprosy, on the other hand, are found *only* in patients suffering from this disease. I would not express any doubt, by this comparison, of the morbid agency of the trichina, but would merely call attention to the fact that for this belief we have really no more conclusive evidence than we have for accepting the pathogenetic influence of bacteria in leprosy and in several other diseases. Yet it will doubtless be years before some of us realize the fact that in this unreasoning and prejudiced opposition to demonstrated facts, we are playing the unenviable rôle of the cow to the locomotive of advancing science. George Stephenson's prophecy—that the result of such collision would be "bad for the cow"—has been often fulfilled; neither horned cattle nor pseudo-bacilli have materially retarded the progress of science. The improvement of means and methods for minute investigation has ever been and must still be followed by further advance into the realm of the minute, whose boundaries doubtless stretch far beyond the present means of optical exploration. After centuries of controversy the intestinal worms banished the "vermicular diathesis;" the acarus scabiei conquered the "itch cachexia;" the step from the acarus to the bacillus tuberculosis is not quantitatively greater than from the tape-worm to the acarus; each is merely the measure of successive improvements in means for minute observation. Yet the same spirit which nurses the vermicular and itch diatheses, will doubtless for years see in bacteria only fibrin threads and fat crystals; and will cling with heroic devotion to the tubercular diathesis, to "micronecrosis," and to narrow lymph-spaces.

When we glance over the progress of the last few years; when we consider the life-saving revolution in surgical methods; when we regard the enhancement, indeed the very salvation of enormous economic interests by the eradication of the bacterial disease of silkworms, without mentioning preventive vaccination against anthrax and chicken-cholera, we may search in vain the records of other departments of science during the same period for discoveries which have secured direct personal and pecuniary advantages comparable to those derived from our present incomplete knowledge of the relations of micro-organisms to disease. And when we consider the problems already half solved, the questions to whose solution the way appears open through the same methods already successfully applied to anthrax and tuberculosis, we may hope for results to which present knowledge shall seem a mere introduction. But these results can be secured only by earnest, skilful, continuous experimental investigation, which is practically impossible without pecuniary support. In France and Germany such support is liberally supplied by the government; in the United States, where human life is certainly as valuable as there; where live-stock interests are already greater than in these countries combined, and must multiply many fold in the immediate future; where a single infectious disease of cattle has caused the loss of \$20,000,000 in one year, and a single disease of hogs the destruction of \$30,000,000 in the same time; where infectious diseases are so prevalent among live stock that the fear of infection has closed European markets against American meat and cattle—the government of this great commonwealth, which advances enormous sums for local river and harbor improvements; which sends expensive commissions over the world to observe the transit of Venus or of the moon; to find an open Polar sea; and engages in other undertakings of purely scientific interest, has not yet made one judicious, systematic, liberally supported inquiry into the possibility of acquiring protection

against pleuro-pneumonia, hog-cholera, and other devourers of the national wealth. A glance at the Imperial German Health Bureau and its work during the last four years, and a mental comparison of the pecuniary resources of Germany with those of the United States, inspire the hope that we shall not always lag so far behind in matters which appeal to the tenderest spot of the American anatomy—the pocket.

In concluding these lectures, Mr. President and gentlemen, I shall offer no apology for their fragmentary character, since I would not call attention to defects already amply apparent. Yet I venture to hope that one merit may be accorded them—that they constitute an impartial and unpartisan attempt to portray the present status of this vexed question. And this I hope, not on personal grounds, but because a suspicion of insincerity in the portrayal would retard acquiescence in what I must and do regard as truth.

If these lectures shall serve as a vehicle for conveying to the busy practitioner facts which he has not time to seek amid the mass of current literature; shall contribute, however little, to the more general discrimination between theories and facts, between observations and deductions, between assertions and demonstrations; shall tend to confirm the belief that much may be hoped for, though perhaps but little is already completed in this direction—their object will be accomplished, and your lecturer will hope that he was not inexcusably presumptuous in consenting to appear upon a platform which has been honored by a Bartholow and by a Dalton.

APPENDIX.

The following cuts are copied from some of the twenty-eight photomicrographs exhibited at the lectures. It has been deemed advisable to print them here with the briefest possible summary of the remarks which accompanied their exhibition.

In erysipelas the lymph-spaces just at and in front of

Fig. 9.—Skin excised, *intra vitam*, from a case of erysipelas; micrococci in lymph-vessel, $\times 700$. (Koch.)

the advancing edge of the inflamed area contain micrococci. These organisms have been isolated by cultivation on solid media (Koch's method) by Fehleisen. He reports the successful induction of erysipelas by inoculation with the micrococci thus isolated, in eight rabbits and in one human patient.

Recurrent or relapsing fever is characterized by the presence of Obermeier's spirillum in the blood.

As yet no successful inoculation with the isolated spirilla has been reported.

A short, thick bacillus is found post-mortem in the

liver, kidney, spleen, and lymph-glands in the majority of cases of typhoid fever (Eberth, Koch, Friedländer); and larger bacilli in the vicinity of the intestinal ulcers (Klebs). Maragliano asserts the presence of both varieties in blood drawn by a hypodermic syringe from the spleen in fifteen cases (*intra vitam*). It would seem,

Fig. 10.—Spirochaete of Obermeier and human blood-corpuscles, $\times 700$. (Koch.)

however, that he protests too much; for even post-mortem only Eberth's, never Klebs' bacilli, are found in the spleen.

In croupous pneumonia small bacteria have been found at the edge of the advancing inflammation (like the micrococci in erysipelas); also in some internal organs. The same bacteria have been found in the lung immediately post-mortem, and even *intra vitam*.

Fig. 11.—Kidney, typhoid fever; masses of bacilli in intertubular capillaries, $\times 100$. (Koch.)

Endocarditis ulcerosa seems to be one of the forms of pyæmia, sometimes of spontaneous (*i.e.*, undiscovered) origin.

The internal organs as well as the cutaneous tubercles of patients afflicted with leprosy contain a distinct bacterium—the bacillus lepræ. Attempts to induce the disease in the lower animals by inoculation with the isolated bacilli as well as with leprosy tissue, have not as yet been successful.

Frisch, of Vienna, has found a characteristic short, thick bacillus in every case of rhinoscleroma (twelve in

number) which he has had opportunity to examine. Pieces were excised from the nose or mouth *intra vitam*; the bacilli occur, like those of leprosy, in the large cells characteristic of the tissue. Frisch cultivated these organisms on solid media, after Koch; but was unsuccessful in attempts to induce the disease in rabbits. It must be remembered that man is the only animal known to suffer from rhinoscleroma and from leprosy.

Fig. 12.—Edge of bacterial colony in the liver from typhoid fever; the individual bacilli are seen, $\times 700$. (Koch.)

Klebs and Crudeli assert the induction of malarial fever in rabbits through the agency of a bacterium—the bacillus malariae. Dr. Sternberg, U. S. A., has made a critical and experimental review of this work, from which he concludes: "The evidence upon which Klebs and Crudeli have based the claim of the discovery of a bacillus malariae cannot be accepted as sufficient," and "their conclusions are shown not to be well-founded."

Fig. 13.—Intertubular capillary of kidney containing bacteria; from a case of croupous pneumonia, $\times 700$. (Koch.)

Such is the general opinion, so far as I have been able to ascertain, among those familiar with this department of investigation. Bacteria said to be identical with these have been found in the blood of patients suffering from malarial fever, and by Ziehl in one individual who had no symptoms nor history of intermittent fever, but was suffering from diabetes. In three of Ziehl's four cases, the bacilli disappeared from the blood after the administration of quinine for several days.

Bacteria of various kinds have been seen in syphilitic tissues, post-mortem, by different observers. Quite recently Birch-Hirschfeld announced the discovery of micrococci in twelve gummata, post-mortem; in three condylomata, one chancre, and one cutaneous papule excised during life. Morison, using aniline staining and Abbé illuminator, found bacilli in chancres and other syphilitic tissues—the same variety being present in all.

Fig. 14.—Incipient abscess formation around a vessel occluded by a micrococcus colony. Heart-muscle, endocarditis ulcerosa, $\times 100$. (Koch.)

The contents of variolous pustules, like other pus often contains micrococci. No trustworthy observation of the presence of bacteria in the blood during this disease has been recorded. Ehrlich has sought them in vain even in hemorrhagic small-pox. Post-mortem they are sometimes found in the tissues.

In diphtheria micrococci are often found not only in the local necrotic tissue, but also in internal organs and in the blood. In scarlatina no reliable affirmative observations have been made, so far as I am aware. But

Fig. 15.—Micrococci in renal capillary, small-pox, $\times 700$. (Koch.)

since diphtheria, scarlatina, and erysipelas must be classed according to clinical, experimental, and chemical (Brieger) evidence with the putrid diseases, the evidence in favor of the bacterial origin of septicaemia and pyemia suggests analogous etiological influences for these diseases also.

Schütz and Löffler have recently reported the induction of glanders in rabbits and in two horses by inoculation with bacilli isolated by cultivation from animals suffering from this disease.

Cuts of the *trichina spiralis* and of the *filaria sanguinis* are added as an illustration of the fact that morphological similarity does not prove physiological identity. These two nematode worms are, of course, easily distinguishable by the difference in size; yet structurally they are, in the larval state as here repre-

Fig. 16.—*Trichina spiralis*, $\times 50$. (Oliver.)

sented, quite similar. Yet the one is found coiled in the voluntary muscles, its migration from the intestine often causing symptoms simulating typhoid fever; the *filaria*, on the other hand, circulates with the blood (by night only, as a rule), and is associated with one of several

Fig. 17.—*Filaria sanguinis hominis* in human blood, $\times 280$. (In this case from twenty-five to one hundred worms were found in every drop of blood between six P.M., and five A.M.)

morbid states—chyluria, lymph-scrotum, sometimes ending in pyæmia (as in the case which I was fortunate enough to observe in the London Hospital). In some cases its presence seems to cause no abnormal symptoms.

Fig. 18.—*Filaria*, dried and stained to show the sheath (compare Fig. 16).

One of the most interesting of recent observations is that of Brieger and Ehrlich (*Berliner Klin. Wochenschrift*, 44, 1882), in which they report two cases of Koch's "malignant oedema" in human subjects suffering from typhoid fever. The bacillus characteristic of this affection is widely distributed, being often found in or-

dinary garden earth, and frequently appearing in animal bodies a few hours after death; in these two cases the organisms seem to have been introduced by subcutaneous injections of musk. Koch and Pasteur have induced the disease in mice and rabbits by inoculation with earth and with the isolated bacilli; and the morbid condition which often appears spontaneously in cattle, termed charbon symptomatique, or Rauschbrand, seems to be the same disease; but this is, I believe, the first instance in which the bacterium has been demonstrated in the human subject of the disease.

EQUINE SCARLATINAL VIRUS AS A PROPHYLACTIC AGAINST HUMAN SCARLATINA.

By J. W. STICKLER, M.D.,

ORANGE, N. J.

IN the endeavor to discover in the lower animals an agent possessed of a power to so affect the human tissues when implanted in them as to render them insusceptible of certain contagious diseases, it is necessary to determine that such an agent represent in a more or less modified form a morbid principle giving rise to a disease in man similar to the one of which this modified microzyme is the exciting cause in the lower order of animal life. The investigations of Cheveau¹ have proven that the contagium particles of small-pox have their counterpart in the active contagious poison of cow-pox, and that the two diseases, although different in degree of intensity, are identical as regards their nature. To prove their identity he inoculated a cow with some variolous matter. There resulted a papule at the point of puncture, unaccompanied with any marked constitutional disturbance, from which he collected some lymph. With this he inoculated a child, getting as a result a vesicle in every respect similar to the vesicle of cow-pox, and this was followed by a general eruption similar to, but milder than what follows a direct inoculation with human small-pox virus. He also failed to produce variolous papules on cows which had already been vaccinated. On the contrary, cows which had neither been vaccinated nor had cow-pox were readily variolated, subsequent vaccination having no effect, proving that immunity had been secured.

Jenner believed in the identity of these two diseases, and that they originated in the "grease" of the horse. If, then, these two diseases, so different in intensity, are due to the same morbid poison, it seems highly probable that the conditions of the tissues, in the case of the cow, exerted constantly a modifying effect upon the poison, while in man the fertility of the disease was not lessened. The fact stands, then, that variola passes through a very modified course in the cow, and probably if the variola were passed from one cow to another for several generations, the modification produced would be still greater. This is rendered more probable by some of the modifications produced on races by crossing. "Lord Orford," says Mr. Darwin, "crossed his famous stud of greyhounds once with the bulldog," which breed was chosen from being deficient in scenting power and from having what was wanted, courage and perseverance. In the course of six or seven generations all traces of the external form of the bulldog were eliminated, but courage and perseverance remained. In this instance the most marked effect was produced in the first cross; but from repeated breeding with the greyhound, one character after another was lost, and only one or two remained permanent. Similarly with regard to the variola, it is probable that the greatest effect would be produced by the first inoculation, and that by subsequent inoculations from cow to cow some characteristics would be lost until

¹ Twelfth Report of the Medical Officer of Privy Council: Dr. Sanderson's Essay, p. 237.

finally a modified pox would be produced which would become natural to the cow.¹

But it has not been necessary to institute a series of experiments to produce a form of variola of the desired type, this result having been reached without any effort on the part of science, and suddenly brought to light by comparatively recent discovery. It remains to ascertain if the same result has not obtained in the case of scarlatina. Thomas² states that it is believed that animals may be affected with a disease corresponding to scarlatina in man. Zurn says that Spinola has observed it in the horse. Williams³ believes in the existence of such a disease in the horse, and gives the following description of its most common forms: First, scarlatina simplex. On the third or fourth day, or even as late as the sixth, after the commencement of epizootic catarrh, the animal is seen to be covered with blotches upon the face, neck, body, and extremities. The blotches elevate the hair, but in many places there is scarcely any elevation of the skin, for if the hand be passed lightly over the apparent swellings, the skin is felt to be but little altered. In other parts of the body, particularly upon the inner aspect of the thighs, actual elevations of the skin in the form of rounded pimples can be seen and felt. The nasal membrane will be covered with scarlet spots of variable size, and there will be a discharge from the nostril of at first a thin serous mucus, which afterward becomes yellow or yellowish brown. The limbs are generally swollen, and the animal stiff in consequence. In some instances no eruption is present, and the only evidence of scarlatina is found in the Schneiderian membrane, and, perhaps, the membrane of only one nostril will be covered with minute scarlet spots.

Soreness of the throat is almost a constant symptom, and if it has preceded the rash, it will in all probability be more or less increased; but it by no means follows that soreness of the throat will appear concomitant with the rash. In a few days the rash and scarlet spots begin to disappear, and on the rash declining, some desquamation of the cuticle takes place, the skin becoming scurfy and the coat remaining dirty for some time. In scarlatina angiosa he states that, in addition to the symptoms already given, there are the following: swellings upon the body and face, petechial spots of a purple hue upon the nasal mucous membrane more intense, severe sore throat, enlargement of lymphatics about the neck, elevation of temperature, acceleration of pulse, rapid breathing, scanty urine, constipated bowels, but no renal dropsy or albuminuria as in the human being.

If, then, this be a true scarlatina and identical with human scarlatina, may it not manifest itself in a modified form when grafted onto the human tissues? To determine, if possible, whether this be true or not. I performed the following experiments: The "nasal mucus" kindly sent me by Professor Williams, of Edinburgh, with which I made the inoculations, I examined microscopically and discovered that it presented the appearance shown in Fig. 1. The large polygonal cells were quite abundant, and scattered about the field were many minute glistening granules, yellow in color, strongly refracting the light. Besides these granules there were larger spherical bodies, about one-third the size of pus corpuscles, and slightly granular. Larger corpuscles, granular, and about as large as pus corpuscles, were quite numerous. Of this fluid I injected with the hypodermic syringe into the subcutaneous tissue of four rabbits and one dog, about six minims, getting as a result within forty-eight hours a confluent eruption, scarlet in color, which existed about four days. After its disappearance there was slight furfuraceous exfoliation. The temperature during the time the eruption was out, ranged between 100° F. and 102° F. Appetite was poor and the animals were disposed to keep very quiet. On the

third and fourth days the dog had a thin mucous discharge from the nostrils while the rabbits had merely a slight redness of the mucous membrane of the nose. There was an enlargement of the lymphatics nearest the point of puncture. A complete return to the normal condition was reached by the eighth day. Microscopic examination of the blood from day to day showed an increase in the number of leucocytes, and on the third

Fig. 1.

day small round granules could be seen, bright in appearance, of a pale red color, and adherent to the circumference of the white corpuscles as seen in Fig. 2. On the sixth day these granules could not be found. I next injected under the skin of these animals several drops of human scarlatinal blood taken from the arm of a boy who had at the time a bright confluent eruption

Fig. 2.

over both arms, chest, and neck. There was not subsequently any local or general disturbance.

To determine the worth of such experiments, it must be ascertained if the scarlatinal poison resides in the blood. The investigations of Coze and Feltz throw light on this point. They introduced a small quantity of blood under the skin of sixty-six rabbits; of these sixty-two died in the course of from eighteen hours to fourteen days, having had high temperature, then diarrhoea and emaciation, and

¹ Ross: The Graft Theory of Disease, p. 121.

² Ziemssen, vol. ii., p. 166.

³ Williams: Principles and Practice of Veterinary Medicine, p. 376. J

the remaining four only recovered after an intense fever. Reiss injected a few drops of blood taken from the arm of a patient dying of scarlatina under the skin of the back of a rabbit, causing its death in twenty-four hours. Further inoculations with this rabbit's blood gave rise to identical results. It seems probable, therefore, that the blood does contain the contagium particles of this disease, and that it is capable of producing a specific effect when implanted on foreign soil.

I next vaccinated twelve patients who had never had scarlatina, with the following results:

CASE I.—Leopold W—, aged seven. Patient of Dr. Carl Büttner, of Orange, who submitted him for vaccination. Vaccinated in right thigh with equine virus. Twenty-four hours later there appeared a punctate redness about the point of puncture. Lymphatics in right groin enlarged. Temperature, 99° F. No general disturbance. By the third day eruption had extended so as to cover a space about as large as palm of hand. On drawing a pair of blunt-pointed scissors across the skin a distinct white line was left, which remained about one minute. The red punctate appearance had disappeared by the sixth day and was immediately followed by desquamation of the epidermis, the period of exfoliation lasting about one week. Slight induration at point of puncture after desquamation. I then injected into the left thigh a few drops of scarlatinal blood, having microscopically such an appearance as is seen in Fig. 3. This

Fig. 3.

blood was kindly furnished by Dr. J. W. Andrews, of Newark, N. J. The blood-globules were crowded together in such a manner as to make some of their number appear oblong, while to their surface there were many small round or oval red globules attached. Besides these there were a few masses of matter without definite outline, looking something like mucin. A specimen of human scarlatinal blood given me by Dr. George Bayles, of Orange, had the same characteristic appearance. The injection of this blood had no effect locally or constitutionally.

CASE II.—Barney F—, aged eleven. Vaccinated with equine virus in right arm. Same local changes as in preceding case. No constitutional disturbance. Injection of human scarlatinal blood into opposite arm produced no effect.

CASE III.—Kate F—, aged eight. Vaccinated with equine virus in right arm. Punctate redness not very extensive, but well marked. White tracings distinct on second day. Desquamation beginning on fifth day. Subsequent inoculation with human scarlatinal blood without effect.

CASE IV.—Edward F—, aged six. Vaccinated with equine virus in right arm. Twenty-four hours later, there appeared an intense redness with bright red spots scattered here and there. On drawing the finger-nail across the skin, a white line was left. Duration of eruption about four days. Desquamation complete. No effect produced subsequently by injection into opposite arm of human scarlatinal blood.

CASE V.—Michael F—, aged twelve. Vaccinated in right arm with equine virus. Area of eruption greater than in any preceding case. Lymphatics more decidedly enlarged. Slight pyrexia. Cuticle exfoliated in quite large flakes. Inoculation in left arm with human blood had no effect.

CASE VI.—Kate C—, aged thirteen. Vaccinated with equine virus in right arm. Eruption not very decided, although apparent, and on the second day the white tracings were easily made. Furfuraceous desquamation. No effect produced afterward by inoculation with human blood.

CASE VII.—Daniel C—, aged ten. Vaccinated in right arm with equine virus. Confluent redness, dotted at irregular intervals with fine bright red points. Second day white tracings, and after disappearance of eruption, the epidermis desquamated. No symptoms produced subsequently by injection of human scarlatinal blood into left arm.

CASE VIII.—James C—, aged seven. Vaccinated right arm with equine virus. Same local changes as mentioned in preceding case. Inoculation with human scarlatinal blood without effect.

CASE IX.—John C—, aged seventeen. Vaccinated in right arm with equine virus. Area of eruption about as large as hand. Small bright red points quite numerous. White tracings very marked. Inoculation afterward with human scarlatinal blood had no effect.

CASE X.—Wm. H—, aged five. Vaccinated in right arm with equine virus. Eruption, white tracings and desquamation all well marked. No effect followed injection of human scarlatinal blood.

CASE XI.—Martin H—, aged eight. Vaccinated in right arm with equine virus. The eruption during the second and third days was quite intense, with enlargement of axillary lymphatics. Redness disappeared momentarily on pressure. Desquamation in small scales. Inoculation with human scarlatinal blood without effect.

CASE XII.—Catherine D—, aged twenty-five. Vaccinated in right arm with equine virus. Redness developed in about twenty-four hours, was intense and punctate. White tracings distinct. Furfuraceous exfoliation beginning on the seventh day. No effect produced by injection into opposite arm of human scarlatinal blood. An examination of the blood during the time the eruption was out showed the red globules to be larger than those seen in normal specimens, crowded together edgewise, and occasionally having attached to their borders small, round, shining bodies as seen in Fig. 4.

The points of interest elicited in these twelve cases are:

First.—The safety in using subcutaneously the virus obtained directly from the horse.

Second.—That when this virus is implanted in the human tissues, there follows a local eruption similar to that seen in mild cases of scarlatina.

Third.—The system appears to be protected against the action of the human scarlatinal poison after vaccination with the equine virus.

May it not be possible, then, that the scarlatinal poison has undergone such modification in the tissues of the horse as to have reached a degree of fertility which renders it, when grafted onto the human tissues, prophylactic against the more malignant form of scarlatina as developed spontaneously in man? Ross makes the following statement: "The disease (scarlatina) may be grafted upon some of the lower animals and by transmission through the same species for a few generations a modi-

fied form may be obtained, which, when grafted upon man will produce a disease so mild as to be entirely innocuous, and yet afford a sufficient protection against the natural variety." But may not equine scarlatina be to human scarlatina, because of modifications already wrought, what cow-pox is to small-pox, in consequence

Fig. 4.

of some change in its fertility brought about long ago? Whether this be true or not, the investigations which I have thus far made seem to possess some points of special interest, and I therefore submit them to the consideration of the profession, and from time to time, as I am enabled to continue these experiments I shall report the results in the hope that they will confirm those already given.

A CASE OF DALTONISM AFFECTING ONE EYE.

By R. W. SHUFELDT,
CAPTAIN MEDICAL DEPARTMENT, U.S.A.

JACKSON BARRACKS, New Orleans, at the present writing, is garrisoned by two batteries of U. S. Artillery. From time to time it becomes necessary to recruit this force from such material as presents itself, and my duty as one of the attending surgeons stationed here is to conduct the physical examination of these men.

In the case of each subject the examination of the eyes is invariably completed by submitting him to the test for color-blindness, using for this purpose the Berlin worsteds, and following the method as prescribed by Professor Holmgren.

Since the middle of last October some thirty recruits have been examined. Of this number three were completely color-blind, one momentarily red-blind, exhibiting like symptoms with such cases as described by Dr. Jeffries, and the subject of this article.

On December 12th last, W. S— (white) was physically examined by me as prescribed by the regulations of the service. He was twenty-one years of age; born in England of healthy parents. No history of syphilis or other disease; had never received any bodily injury, and, in fact, his general examination was satisfactory. He was next required to read the number of spots on the test-cards at twenty feet. This he promptly did with both eyes open, and equally well with his right eye, but upon closing this the left one was discovered to be markedly myopic. This defect disqualified him as a recruit. Still, never allowing an opportunity slip to examine into a candidate's sense of color-perception, I directed him to step up to the table where the worsteds

were spread out. With both eyes open he, without trouble or hesitation, picked out series of purples and greens to match the test-shade, but exhibited a good deal of uncertainty when called upon to do the same for the reds, the test-color being a bright red-lead shade. The worsteds being again mixed up, he successfully chose the purple and green shades with either eye, one or the other being closed, and the reds with his right eye, the left one being closed. Mixing up the worsteds once more, and firmly shutting his right eye, he was asked to pick out the red shades. This he essayed to do by first selecting a pale shade of brown, placing it one side, and, with considerable hesitation of manner, he proceeded in the same way until he had laid aside a full series of brown shades from dark to a light ochre. It was amusing to see his confusion when I suddenly released his right eye, as the lids were kept together by my finger, and quickly closing his left, allowed him to see what he had done.

The experiment was tried several times, the worsteds being thoroughly mixed up each time, before he was completely convinced that he had some defective color-sense in one eye that he could demonstrate himself with the opposite and sound one. Not having the opportunity then, I exacted a promise from him to return next day, upon which occasion I proposed to make a complete record of his case, but he never returned, and this is all I can ever be able to offer illustrating this singular and interesting condition.

TWO CASES OF INJURY TO THE CARDIAC VALVES FROM SUDDEN VIOLENCE.

By WM. L. AXFORD, M.D.,

CHICAGO, ILL.

INJURIES to the valves of the heart are of so rare occurrence that the two cases which have come under my observation during the past two years seem well worthy of report.

The literature of the subject is extremely meagre, and, in the limited amount to which I have access, I have been able to find very little more than a mere mention of the fact that such accidents do occur. Dr. C. Hilton Fagge ("Diseases of the Valves of the Heart," in "Reynolds' System of Medicine") briefly discusses this subject.

Corvisart was the first to point out that this injury was possible and that it could be caused by muscular effort. Dr. Peacock in 1865 had collected seventeen cases, four coming under his own observation. These were all cases where the previous condition of the patient had been good, with no history of rheumatism or suspicion of previous cardiac disease. The valves injured were as follows: aortic valves, ten times; mitral, four times; tricuspid, three times.

The two cases which I wish to report seem to be worthy of classification with those of Dr. Peacock, since both patients were young, both had previously enjoyed good health, both were able to perform severe manual labor before the accident.

To Dr. C. A. Babcock, of Detroit, in whose practice the first case occurred, I am indebted for the particulars as well as for permission to report it.

CASE I.—J. G—, aged sixteen, well developed. While carrying a heavy weight made a sudden and severe muscular effort. Soon complained of considerable pain in the centre of the sternum, also of an uncomfortable feeling in the left arm. Expectored some blood, short dry cough. Before coming under Dr. Babcock's care he had been treated for dyspepsia. His condition then was as follows: Pulse, 100; temperature, $97\frac{1}{2}^{\circ}$; respiration, 26; irregular. Skin had peculiar brown hue. Complained of a dull rumbling sound in his ears. Urine loaded with urates. Auscultation revealed an aortic regurgitant murmur, partially obscuring and following the second sound of the heart. After treatment for some time the subjective symptoms disappeared but the mur-

mur was still to be heard. He was seen by Professor Palmer, of the University of Michigan, who confirmed Dr. Babcock's diagnosis of rupture of an aortic valve. Here it was my good fortune to see the case. At the present time the boy is able to earn his living as a book-keeper, but is unable to do manual labor.

The second case was presented by Dr. Robert Johnston, of Milford, Mich., before a local society with the following history:

CASE II.—A. M—, aged fifteen. Previous history good. No rheumatism before his present trouble occurred. Was cultivating when his horses became suddenly frightened. To regain control of his team he was obliged to make a violent muscular effort. His feet sank deeply into the soft ground and one was so injured that an abscess formed in the plantar surface. He was very much fatigued by his exertions, he immediately felt pain in the region of the heart, and says he could not get his breath for several days. On several occasions when he became excited or attempted any muscular effort dangerous symptoms followed, syncope and a sense of impending suffocation. He was treated by various local physicians, and at some time during this period was said to have had "subacute rheumatism affecting the large joints, the back, and many of the lesser joints." Exactly what the nature of this complaint was I am unable to determine. He finally fell into the hands of Dr. Johnston, who first recognized the true nature of his trouble, and by the use of digitalis was able to relieve his symptoms to a considerable extent.

He is able to be about but cannot make any physical exertion beyond what is absolutely necessary, and is obliged to be very careful in his habits.

All were agreed that the physical signs were those of mitral regurgitation, but the question of etiology elicited considerable discussion. With the previous case fresh in my memory, taking into consideration the history of the present case, I had no hesitation in pronouncing it a case of rupture of a mitral valve. Some present were inclined to the theory that the obscure rheumatic trouble was the important etiological factor, but the patient says that all his subjective symptoms dated from the moment of the accident.

That a careful physical examination was not immediately made is to be regretted, nevertheless it seems to me clear enough that this case can be safely classed with the one first mentioned as an example of injuries to the cardiac valves from violent muscular efforts.

MONSTROSITY OF A HAND.

By DAVIS HALDERMAN, M.D.,

PROFESSOR OF SURGERY, STARLING MEDICAL COLLEGE, COLUMBUS, OHIO.

THE subject of this strange anomaly was a male, forty-three years of age, a native of Bavaria, in Germany.

The account he gave of his deformity, as gathered from his parents, was to the effect of his having been born with his right ring finger as "big (?) as a man's;" and that, because of its unsightly character, it was amputated by a surgeon when he was but nineteen weeks old; whereupon the middle and little fingers, together with their part of the carpus and metacarpus, which, up to this time, were all of natural size, now took to growing much faster than the rest of the hand, and this growth, he further states, was kept up until his thirtieth year, when said parts had attained their present magnitudes, which were as follows: The little finger was $4\frac{5}{8}$ inches long, and $5\frac{1}{4}$ inches in circumference at its first, and $4\frac{3}{8}$ at its second phalanx, and nearly the same at its last. It was completely ankylosed in a straight position at its phalangeal articulations, and allowed but a moderate degree of passive motion at its metacarpal junction, from which latter it stood off at right angles with the axis of the hand in a ghastly and repulsive manner. Its encumbrance, to say nothing of its uselessness, may be judged

of from the fact that the distance from its tip to the end of the thumb, when the hand lay at rest upon its palm, was $11\frac{1}{2}$ inches. The same finger of the opposite side was only $3\frac{1}{2}$ inches long, and otherwise of normal proportions, as were also the rest of the digits of this hand.

The malformed middle finger measured $5\frac{1}{2}$ inches in

length by $5\frac{1}{2}$ in its greater, and $4\frac{1}{4}$ in its lesser circumference; but it was considerably constricted at its base. It occupied a uniformly lateral curved position, and was semiflexed; the former, which was considerable, and toward the radial side, was due, evidently, to the preponderance of the morbid growth on its ulnar aspect, thus forcing the finger round upon itself in the opposite direction, similar to what takes place in the distortion

outward (hallux valgus), sometimes, of the great toe, from hypertrophy of the bony factor of its metatarso-phalangeal joint on the inner side alone. Save at its metacarpal junction, this digit, too, was completely ankylosed, and looked more like a vast claw than a human finger. It, also, was worthless, except a sort of hook-like purpose that it served.

The metacarpal region of this hand, exclusive of the thumb part, measured eleven inches round; but its pre-natural size was confined to the three inner ranges. It was made up of bone and soft parts in their relative proportions; the latter, which seemed to consist largely of adipose tissue, formed a vast, cushion-like eminence at this place, in striking contrast with the thenar side, whose group of muscles was almost completely atrophied, leaving quite a pit, instead of the prominence that normally characterizes it. This, it was stated, took place along between the nineteenth and twentieth years, and it, of course, left the thumb in a greatly enfeebled condition. No exciting cause could be assigned for it.

A similar measurement of the opposite metacarpus gave only eight and one-half inches.

The cicatrix left from the removal of said ring finger was of linear shape, extended in an antero-posterior direction, and was two and one-half inches long, showing, therefore, that it must have grown *pari passu* with the growth of the malformation, verifying thus the old adage, that a scar in childhood, as long as the little finger, will be so still in adult life; and moreover, that it holds as well in morbid as in natural growths.

A no less interesting feature of this case was the discrepancy that existed in the lengths and magnitudes of the upper extremities above the wrists, as the following comparative measurement will show:

TABLE OF COMPARATIVE MEASUREMENTS OF UPPER EXTREMITIES.

	Anomalous side.	Sound side.	Difference.
	Inches.	Inches.	Inches.
Acromion process to head of ulna	20	21½	1½
Acromion process to external epicondyle of humerus	11½	12½	1
External epicondyle of humerus to head of ulna	8½	9½	1
Circumference of forearm at smallest part near wrist	8½	7	1½
Circumference of forearm at muscular part near elbow	11½	9½	2
Circumference of upper arm	9½	9½	0

This preponderance in the size of the forearm was confined to its inner side, and was made up of bone and muscle in their relative proportion, the latter being finely developed, and free from adipose. The ulna, as compared with its fellow upon the opposite side, and with its associate radius, was truly massive. The prominence of its subcutaneous portion, especially its head, as viewed from behind, was so striking as at first sight to be strongly suggestive of luxation of this end of the bone backward upon the radius. Its olecranon process, too, was preternaturally salient, and gave to the elbow a distorted contour.

The man declared this forearm to be the stronger, which, judging from the above, was doubtless true, despite the crippled condition of the hand.

From the foregoing it will be seen (1) that the anomalous growth above the wrist was of thickness only, not of length; (2) that the latter, on the contrary, fell even below the normal, (3) but that it was more than made up in the hand, taking the elongated little finger as a guide, to say nothing about the inner carpal and metacarpal ranges, which, it might have been observed, were also somewhat lengthened; (4) that this growth in thickness took its rise in the olecranon process, (5) and in travelling down kept to its ulnar side, until the hand was reached, (6) when it overstepped the bounds recognized in the correlation of the different parts of the latter and the forearm, the middle finger, belonging as it does to the radial side, being included in the enlargement, though not to the same degree on both sides; and again, (7) that the digital distortions followed the lines of abduction until the hand became spread out like a vast paw, or, as remarked by one, "like the foot of a large ostrich."

The man was otherwise sound. He was of medium size, well built, and of average intellectual endowment.

Notwithstanding crippled as it was in its individual members, except the index finger, which alone was sound, the hand as a whole was of considerable use, the man being enabled, as a common laborer, to gain a livelihood for himself and family; and it is worthy of note that he has six children, normal in all their parts. Nor could any irregularity be traced in his genealogy or maternal impressions during his gestation.

The occasion of his coming to our notice was a slight frost-bite of the monster small finger, on account of which, and of its being useless anyhow, he desired it amputated, which was accordingly done, drawings, casts, etc., of it having been previously secured.

Many queries naturally arise in connection with this case. It would be interesting to know (1) what, primarily, determined the nutritive activity that was evidently at the bottom of it; (2) why, in the forearm, it was confined to the ulnar side, but at the same time was exercised in one direction only, and fell short in the other; (3) while in the hand, it extended abnormally in all, (4) why the process should have been maintained for so many years, and meantime been deficient in another part of the same hand, and (5) what, if any, influence the removal of said ring finger had on the subsequent growth, etc.

The circumstance that the area of hypertrophy corresponded with the distribution of the ulnar nerve, points to it as an agency in the trophic action. Still, it does not answer the question as to the *fons et origo* of this queer development, and of its eccentric course; its falling short of the normal here, and going beyond it there; and finally, that in the same part it should be in excess in one direction, and deficient in the other.

As showing the nutritive activity even at this age, it may be observed that the hemorrhage from the digital artery of the enlarged little finger, at its amputation, was as free as ordinarily takes place from the dorsalis pedis.

It may be further mentioned that the fatty tissue here, too, was in excess; the bones, also, were very large; but the muscular element was poorly represented, as might be expected, from its non use.

Progress of Medical Science.

THE BACILLUS TUBERCULOSIS IN THE URINE.—Dr. Victor Babes, of Buda-Pesth, Hungary, found the bacillus of Koch in the pus-corpuscles of the urine of two persons during life, where post-mortem examinations revealed tubercular disease of the kidneys and bladder. In a third case, where no abnormality could be made out in the lungs, but where Professor Verneuil, of Paris, nevertheless suspected tubercular disease of the urinary apparatus, Dr. Babes examined the urine and found the bacillus. No autopsy has as yet been made in the last case.—*Orvosi Hetilap*, February 18, 1883.

MUCOUS POLYPUS OF BLADDER IN A CHILD.—At a meeting of the London Pathological Society Dr. Shattuck exhibited a growth which came from the bladder of a girl, and exactly resembled a nasal mucous polypus in its histological characters. A long process occupied the urethra. The pelves of the kidneys were dilated, but the renal substance was healthy. The case was a fit one for surgical treatment, but unfortunately the patient died from exhaustion before an operation could be performed.—*British Medical Journal*.

CYSTINURIA.—Dr. Mader relates the case of a woman, thirty-two years of age, who was seized with a chill, vomiting, and pain in the right hypochondrium after exposure to cold. Nine days later the urine contained a quantity of pus streaked with blood, and gave forth the odor of sulphuretted hydrogen. Microscopical examination revealed the presence of a few beautifully formed crystals of cystine. No calculi were passed at any time, except on one day when a small mass of cystine the size of a poppy-seed was discovered. The pus and the cystine gradually disappeared, and the patient was cured in about six weeks. Dr. Mader supposes that the case was one of renal abscess, possibly caused by the little mass of cystine crystals subsequently discovered in the urine.—*Ber. Rudolph-Stift., Wien*, 1882.

TREPHINING FOR INTRACRANIAL ABSCESS.—Dr. Kilgarriff exhibited a patient before the Academy of Medicine of Ireland on whom he had performed trephining, on account of an abscess resulting from a fall in the hunting field. The patient was unconscious for two hours after the accident. At the end of a fortnight he was removed to Dublin, suffering much from pain over the upper part of the occipital bone on the right side, and also much gastric irritability and general debility. Any motion, such as driving, intensified the pain, and caused nausea. On examination, a shallow depression of the size of a florin, bounded by a well-defined margin, was found at the situation where he complained of the pain. The diagnosis of fracture, with the subsequent formation of an abscess within the cranium at the seat of the lesion, was made. An exploratory incision was made down to the bone, and a small purulent collection was opened. On exploring the bone, a small circular opening through the skull, about two lines in diameter, was discovered. Through this opening, situated on the upper part of the occipital bone, some purulent matter oozed. A circular piece of bone was removed with the trephine, to provide free exit for the pus. An abscess-cavity, from which almost half an ounce of pus welled up, was opened. The inner surface of the piece of bone removed was deeply eroded. The cavity of the abscess was washed out with a weak solution of carbolic acid. Subsequently, the patient experienced an attack of erysipelas of the head and neck, from which, however, he recovered; and nothing further occurred to interrupt the progress of complete recovery.—*British Medical Journal*.

LYMPHOSARCOMA INVADING THE DUODENUM.—Dr. Norman Moore, at a meeting of the London Pathological Society, showed a lymphosarcomatous growth originating in the lumbar glands. They were greatly enlarged, and the mesenteric glands to a less degree. The duodenal wall was greatly thickened, and the mucous surface ulcerated. There were no other infiltrations. The specimen was from a woman, aged forty-one. During life an irregular ovoid tumor was felt in the epigastric region. The greater part of it was dull on percussion; a lesser part was slightly resonant. The dull part was where the duodenum was most thickened by infiltration. The resonant part was where it was dilated. There was no intestine in front of the tumor. The duration of illness was eight months. A pulsation in the abdomen was first noticed, then vomiting after food, and the abdominal tumor.—*British Medical Journal*.

NERVOUS DYSPHAGIA.—A man, thirty years of age, had suffered from childhood with extreme nervousness. He stated that he had always had more or less difficulty in swallowing. But six years ago, in attempting to swallow a piece of meat, he was seized with a severe attack of suffocation. This was repeated a few years later, upon eating a soft-boiled egg. The patient was very excitable, becoming greatly agitated from slight causes. He complained also of a feeling of weakness. The act of deglutition, besides the expression of anxiety, was seen to be accompanied by a general trembling of the entire body. At times there were hypochondriacal delusions. Bromide of potassium, galvanization, the cold douche, and other remedies were tried unsuccessfully. If the patient could be engaged in conversation while eating, the act of swallowing became much more easy. Attempts to introduce a stomach pump, were followed by very great excitement and distress. The patient was finally discharged unimproved.—*Ber. Rudolph-Stift., Wien, 1882*.

THE CAUSATION OF PAIN IN THE LEFT SIDE.—At a recent meeting of the Academy of Medicine, in Ireland, Dr. Beatty read a paper on this subject, drawing special attention to a form not sufficiently recognized, which was due to fecal accumulation, and removed by getting rid of the accumulation. The pain was felt over the lower few ribs on the left side, was associated with extreme

tenderness on pressure upward of the tenth or eleventh rib, scarcely any pain being felt on pressure of these ribs downward, and was relieved when the side was pressed inward with the flat of the hand. He explained its occurrence by the drag of a loaded colon on the pleuro-colic ligament, this constant drag setting up a state of extreme irritability in the nerves of that ligament, so that a painful impression was carried upward along the left lesser splanchnic nerve to the spinal cord, and was transferred, by the law of irradiation of sensations, to the tenth and eleventh intercostal nerves. In the discussion which followed, Dr. Smith said the pleuro-colic fold had not received the attention it deserved. It certainly was of considerable importance in the investigation of abdominal disease. Dr. Beatty's arguments were valid as explaining certain kinds of left-side pain, but did not explain all kinds. Dr. Beatty replied that he did not wish it to be understood that he considered left-side pain was caused in every instance by fecal accumulation, but only in cases presenting the symptoms he had mentioned.—*British Medical Journal*.

TUBERCULOUS NODULE IN THE LUMBAR ENLARGEMENT OF THE CORD.—A coachman, thirty-nine years of age, was admitted to hospital suffering from advanced pulmonary tuberculosis. Eight weeks before admission he had experienced considerable pain in the feet, radiating into the toes and up each side of the leg. There was no ataxia. The spinal symptoms continued to increase. There were retention of urine and involuntary passage of feces, progressive anaesthesia and analgesia, and finally complete paraplegia. The tendon and skin reflexes were abolished. There was a painless effusion into both knees and ankles. Death finally ensued upon symptoms of peritonitis. At the autopsy there was found to be pulmonary, laryngeal, and intestinal tuberculosis with perforation of the bowel. In the lumbar enlargement of the spinal cord, a little to the left of the centre, was found a caseous nodule the size of a bean, surrounded by an area of softening in the medulla.—*Ber. Rudolph-Stift., Wien, 1882*.

HYDATID OF THE BRAIN.—Dr. Hawkins, in the *Australasian Medical Gazette*, reports a case of hydatid of the brain. The patient was a youth, eighteen years of age. He had an epileptic fit on March 25th, but was soon well again. Dr. Hawkins first saw the patient on April 11th. He was then sitting up, complaining of severe pain at the back of the head, a fulness about the throat, and he had a very marked squint—no fever, no vomiting. He said he felt as if another fit were coming on. He was ordered a purge and large doses of bromide, and was to be seen the following day. The doctor, however, received a message to the effect that the boy was much better, would not trouble him to call, but would come and see him himself. He did not appear as promised, but two days later a message came to say he was dead. It appeared that, feeling so much better on the day before—the pain and the squint having both left him—he went out to spend the evening with some friends. He was observed to be in excellent spirits, and thoroughly enjoyed himself, but it was said he did not touch any stimulant. The next morning he was about to get up as usual, but not feeling very well, determined to lie in bed. He complained of a slight return of the pain in the head, but was able to converse until noon, when he quietly turned round in his bed and died, having asked for a drink five minutes before. Prior to the date first mentioned (March 25th) he had never had an epileptic seizure, but on two occasions, at intervals of a year or more, had complained of fainting attacks. He also suffered occasionally from what he considered to be bilious headaches. He was a hard-working lad, engaged in a butcher's establishment, not deficient in intelligence, could draw, play the harmonium, and had a good memory. He had been brought up in Sidney since the age of two years, but his early infancy was passed in Queensland, where the drink-

ing water used by the family was obtained from an open creek through which, at certain seasons of the year, there was considerable traffic of sheep and dogs. The following was noted at the autopsy: skull larger on right side than on left. Calvaria very thin—almost transparent in places—showing plainly marks of convolutions on the right side. Dura mater normal, subarachnoid fluid absent, from the convolutions being so closely pressed together. At the back of the right posterior lobe the nerve-tissue had given way, and from it was seen protruding a transparent bladder distended with fluid. The brain was carefully removed, and the hydatid cyst (for such it proved to be) was found embedded in the substance of the brain tissue, without occupying the lateral ventricle.

ANATOMICAL CHANGES IN BRIGHT'S DISEASE.—From a series of articles in the *Archives Générales de Médecine* Dr. Brault feels justified in formulating the following propositions: 1. The group of symptoms understood by the name of Bright's disease corresponds with a variety of renal changes, acute, subacute, and chronic, which may be either inflammatory or degenerative. 2. These various renal changes may be due to several causes, or one cause may give rise to different forms of the disease. 3. The first cause of the lesions is probably a chemical alteration in the blood, the nature of which is to be determined in each case. 4. To find expression in clinical signs, the anatomical lesions must be situated in the glomeruli and the lining of the convoluted tubules. 5. The only clinical expression of the renal lesions is albuminuria. This point, however, is still questioned by some writers. 6. The other lesions of the kidney (increase or diminution or contraction of the connective tissue, disseminated fatty degeneration, etc.) which determine the physiognomy or gross appearance of the gland, find no clinical expression. 7. The symptoms, other than albuminuria, of the different forms of nephritis depend upon the retention of excrementitious matters in the blood. 8. This retention is due to an anatomical change, producing a disturbance of function in the secreting portion of the kidney. The anatomical changes upon which this functional trouble depends are numerous, such as acute or chronic fatty degeneration, transformation of columnar into flat epithelium, and finally atrophy and progressive disappearance of this epithelium. The latter is seen in interstitial nephritis of vascular origin.

GOUTY TUMOR OF PENIS.—At a recent meeting of the Glasgow Medico-Chirurgical Society (*Glasgow Medical Journal*), Dr. H. C. Cameron related a case in which there was a hard little tumor of gouty origin situated between the dorsal and right lateral aspects of the penis, about an inch from the pubes. It caused no pain except during erection, when there was always severe pain in the part, and the penis became distorted and bent at a sharp angle. He had seen one other similar case.

EXPLORATION OF THE BLADDER BY PERINEAL SECTION OF THE URETHRA.—Sir Henry Thompson, at a meeting of the Royal Medical and Chirurgical Society, read a paper on an operation for exploring the bladder by perineal section of the urethra, and for removing vesical tumor, impacted calculus, etc. The author considered this a new method of investigating obscure diseases of the bladder, which promised to be valuable in certain conditions, occasionally met with. Every one sometimes met with a case in which the symptoms of vesical disease were severe and obstinate, and although very careful examination had been made, he was unable to arrive at a rational diagnosis. The occurrence was doubtless not a common one; in the great majority of cases carefully made observations demonstrated the nature and seat of the disease. But for the exceptional instances, always important—cases generally marked by frequent or persisting hæmaturia of some standing, manifestly not renal, and without local sign of cancerous tumor—he proposed to take decided action, and to submit, further, that such action should not be unduly postponed.

The essential step in the method proposed was to examine the entire internal surface of the bladder with the finger, by which means we could recognize the presence of any tumor, large or small, the existence of encysted calculus, etc. The method of doing this was illustrated, and shown to be a proceeding simple and easy of performance, and at the same time one which involved little if any danger to life. It consisted in making a small opening from the raphe of the perineum to the membranous urethra, which was opened on a grooved staff just enough to admit the left index-finger to enter the canal and to be pushed on to the neck of the bladder. Provided the anæsthesia of the patient was so complete that the abdominal muscles were perfectly relaxed, every portion of the internal surface of the bladder might be brought consecutively by supra-pubic pressure into close contact with the tip of the finger, and any deviation from the natural condition, however slight, could be noted. The operation was an external urethrotomy only, and involved neither the prostate nor the bladder. The application of the proceeding not only to diagnosis but subsequently to treatment was then discussed. It was shown to offer facility for the removal of tumor, impacted calculus, etc. Seven or eight cases in which the operation had been performed were cited, and several specimens of tumor were exhibited which had been removed by the author. These latter were examples of a disease which is inevitably fatal unless removed by operation. Great care was necessary in examining the state of the patients before having recourse to operation. The two conditions, the absence of which were so important to be assured of before interfering, were renal disease and cancer. Hæmaturia from either of these sources of course absolutely contra-indicated an operation.—*Lancet*, January 27, 1883.

VENESECTION TO PREVENT PREMATURE BIRTH.—Dr. Mayo writes to the *Australasian Medical Gazette* to the effect that he has found phlebotomy an efficient preventive of premature births. He recommends that from three to four ounces of blood be abstracted soon after the first indication of quickening. For fifty years he has resorted to this practice with good success. And he adds that he bleeds indiscriminately both robust and delicate women.

TRAUMATIC PNEUMONIA.—Dr. Mader relates the case of a laborer, fifty-eight years of age, who fell from quite a height, striking upon the chest. Ten days after the accident he entered the hospital suffering from severe pain in the epigastrium and right hypochondrium. The liver was enlarged and exceedingly tender. There were also marked signs of pneumonia of the right lung, dullness on percussion, bronchial respiration, and bloody sputa. The disease ran the ordinary course of an idiopathic pneumonia, resulting in complete recovery.—*Ber. Rudolph-Stift.*, Wien, 1882.

ANTAGONISM BETWEEN SYPHILIS AND VACCINIA.—Dr. Polin inclines to the belief (*Annales de Dermatologie et de Syphiligraphie*) that there is an antagonism between the vaccine virus and that of syphilis. He was led to this view by the results of some vaccinations performed by him in Algeria. Of 471 children the vaccination was successful in 410, all of whom were free from any syphilitic taint. Of the 61 children in whom the inoculation did not succeed, 48 presented indubitable evidences of syphilis.

ACUTE INFLAMMATION OF THE INTERNAL EAR.—Dr. Voltolini calls attention, in a monograph published in Breslau, 1882, to the frequency of acute inflammation of the labyrinth (*otitis labyrinthica s. intima*) in young children. He states that it is usually mistaken for epidemic cerebro-spinal meningitis, but that it differs from that disease in its origin, symptoms, and sequelæ. He proposes to give it a place among the diseases of childhood, and argues at length against Politzer and others who deny its existence.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 24, 1883.

CHANGES IN THE RENAL GANGLIA AND BRIGHT'S DISEASE.

DR. SAUNDBY, in the *British Medical Journal*, January 13, 1883, confirms the observations made by Drs. Da Costa and Longstreth, concerning the altered state of the renal ganglia in Bright's disease. But whereas the latter are disposed to regard the neural change as the primary and causative one, Dr. Saundby asserts that the ganglionic nerve-cells are only secondarily affected. Moreover, while the nature of the nerve-change was described by Da Costa and Longstreth as identical with fatty degeneration, Dr. Saundby affirms the process to be one of pigmentary metamorphosis merely. Thus, although admitting the accuracy of their observations, he dissents from the conclusions which they have arrived at. Indeed, he is certainly right in asking why they regard the ganglionic changes as causative factors, more especially in the production of the contracting kidney, since similar nerve alterations are found as well in all the other types of Bright's disease. To quote Saundby's own words, he says:

"I think we cannot escape from the conclusion that the ganglionic lesions stand in the same relation to all the forms of Bright's disease. There is nothing to suggest that they are more likely to be primary in one form than in another; so that, if we hesitate to regard acute Bright's disease as primarily a disease of the renal ganglia, any objections which weigh with us in this case should hold good in all. It may be thought that the insidious mode of origin of the contracting kidney makes it a fairer field for speculation than the other forms of Bright's disease; but I would earnestly protest against the assumption that the obscurity of a problem justifies the introduction of crude hypotheses resting on ambitious facts and doubtful analogies. A moment's reflection, moreover, will assure us that we really know no more of the actual mode in which the kidney is affected by, for example, the poison of scarlatina, than we do of that of gout."

But the question of most moment is whether the nerve-changes, about the actual occurrence of which there appears to be no longer any doubt, are primary or secondary. And the answer to this question has not yet been a satisfactory one. Here, as elsewhere, we should remember that the association of pathological processes does not prove the existence of a causal relationship between them. Dr. Saundby very aptly calls to mind that quite

similar nerve-changes have been described in other more or less obscure diseases. Thus Marcacci has found them in diffuse eczema; Brigidi has described them in pseudo-hypertrophic muscular paralysis and pernicious anæmia; Morselli has noted their occurrence in glio-sarcoma of the brain; Ponicaré in general paralysis of the insane; Pio Foa in cholera. They have also been seen in connection with diabetes mellitus. Moreover, Giovanni, as long ago as 1876, had found cellular infiltration of the sympathetic ganglia in a great variety of visceral and general diseases. The evident inference is that structural changes of organs are commonly accompanied with demonstrable signs of irritation in the ganglia.

Reasoning from analogy, we may therefore assume that the ganglionic lesions of Bright's disease are the results or concomitants of the renal alterations. At any rate, our present knowledge does not justify the assumption that they are in any sense the forerunners of that malady.

This statement is by no means intended to discourage a new line of research. On the contrary, it should stimulate us to further labor in a promising field of pathological inquiry.

DISEASES OF THE FALLOPIAN TUBES.

DR. THOMAS SAVAGE directs attention in the *Birmingham Medical Review*, January, 1883, to the comparative frequency of pyosalpinx as a cause of recurrent attacks of pelvic inflammation. He believes that many cases of supposed pelvic cellulitis hitherto regarded as incurable really come under the head of inflammation of the Fallopian tubes. Such cases he holds to be often curable by operation. Among other causes, he thinks that gonorrhœa may play an important part in the production of Fallopian tube diseases, and in this respect he agrees fully with Dr. Noeggerath, of whose previous publications he seems, however, quite ignorant. The first effect of inflammation seems to be to seal up both ends of the oviduct, giving rise subsequently to an accumulation of serum or pus. In cases of hydrosalpinx the fluid may be absorbed, but this result, Savage thinks, is seldom, if ever, obtained when pus is present. Now, in all such cases temporizing is not only useless, but positively harmful.

The diagnosis of disease of the Fallopian tube is, to some extent, presumptive. There will be found a small tumor in the position of the tube on one or both sides of the uterus, or, if larger, it may be felt almost wholly in Douglas' space. In the acute forms the parts around the uterus may be felt to be boggy, with more or less fixation of that organ. In the more chronic forms, the uterus may be quite free and mobile. In some cases there is nothing to be felt in the pelvis, and the diagnosis is based upon the presence of more or less constant pain and recurring attacks of inflammation. In performing abdominal section for the removal of these tumors, the author recommends that the incision be about two inches in length, or just large enough to admit two fingers. If the tumor be too large to permit of its extraction through this short opening, it is a good plan to aspirate it. If any fluid escape into the abdominal cavity, it is not necessary to wash out the pelvis, but dry sponging should be thoroughly practised. If no pus or blood

have escaped into the peritoneal cavity, the wound should be closed completely, otherwise a glass drainage-tube is to be inserted. Both Fallopian tubes should be removed, even though one be apparently healthy, as the probability is that the normal one would sooner or later become affected in the same way as its fellow. Dr. Savage formerly insisted strongly upon the use of the spray in all abdominal operations. But he has now discontinued its use, believing that increased operative experience and extreme cleanliness are the two main factors which contribute to successful practice.

THE HYGIENIC TREATMENT OF ALBUMINURIA.

THE treatment of chronic Bright's disease by medicines alone has not hitherto been very satisfactory. Witness, for instance, the long list of drugs that have all had their day of popularity, only sooner or later to be consigned to oblivion. Ever since the publication of his well-known treatise, Senator's name is prominently coupled with modern notions concerning albuminuria, which must ever remain one of the most significant symptoms of renal disease. His monograph on this subject is still one of the most elaborate and carefully prepared essays extant. At a recent meeting of the Berliner Med. Gesellschaft, he again took up the subject of albuminuria, more especially as regards the hygienic management of patients suffering from the various forms of Bright's disease.

He urged upon his hearers the great necessity of attention to the details of diet and hygiene in the management of this affection. In this connection he also called attention to the improvements in the condition of subjects of Bright's disease so often seen to follow their admission to hospital. Senator had noticed this amelioration even in cases in which the medical treatment remained precisely the same as that previously followed without effect. And he attributed the improvement solely to the more favorable hygienic surroundings of such patients following their admission to a hospital.

We all know that transient albuminuria is frequently seen even in healthy individuals during the digestion of a full meal. Now, in view of this fact, Senator advises that patients with Bright's disease should never eat heartily at any one time, but should rather take nourishment in smaller quantities at more frequent intervals. In regard to the quality of food taken, he recommends that it be, as far as possible, non-albuminous. Eggs should under no circumstances be allowed. Of meats, those should be given the preference which contain the smallest proportion of albumen, such as veal and poultry. Fish should also enter largely into the dietary. A liberal use of vegetables, with the exception of the leguminous ones, is advised. The popular milk diet is likewise recommended as exhibiting a minimum of albumen. But as milk is also deficient in the carbo-hydrates, Senator allows with it a small quantity of bread, meal, or wheaten grits.

The functions of the skin should be most carefully attended to. A moderate perspiration is to be almost constantly maintained, and to effect this with the least danger to the patient, the speaker advised a more or less prolonged confinement to the bed. This was also recommended on the ground of restraining muscular movements. It was stated that an increase in the amount of

albumen excreted always followed upon muscular exertion. Consequently all active exercise should be forbidden. And if fresh air were deemed necessary it should be taken in a carriage, the patient being well wrapped up to guard against the danger of catching cold.

Senator does not claim that chronic albuminuria can be cured in this way, but he states that he has brought about a marked amelioration of the symptoms through strict attention to the minutiae of the hygienic and dietetic treatment, here briefly outlined. It is questionable, however, how far the subjects of nephritis in the earlier stages would carry out the strict and to them tiresome details of treatment as laid down by the speaker in his interesting address. Such patients are sick, to be sure, but they are not always sufferers. Pain is, after all, the most persuasive reminder of the physician's injunctions. When this is absent or insignificant, his advice is too often neglected, even by the otherwise prudent and intelligent.

As regards the more advanced cases, a cure is, of course, out of the question. Nevertheless, Senator's method may prove of great value in prolonging life, and ensuring a more comfortable existence. Results certainly that the profession will never belittle or despise.

CEPHALIC AUSCULTATION IN MENTAL DISEASE.

DR. ADRIANI (*Journal de Méd. et de Chir. Pratiques*, February, 1883) has been conducting a series of investigations upon the transmissibility of the voice to the occiput, with a view to determine its value as a sign of mental disease. The patient should speak in a low tone while the ear of the auscultator is applied to the occiput. He found that in a number of cases of mental disease the voice-sounds were exaggerated or weakened, amphoric, indistinct, or absent. In healthy individuals they were seldom exaggerated or weakened, and never amphoric or indistinct. He thinks that the sound of the voice is transmitted by the cranial bones and not by the brain substance. The latter, however, influences the sound, and it is probably to the difference in its density that the various modifications of the voice-sounds are due. According to Crichton Browne the density of the brain varies in the different forms of mental disease, and hence Adriani sees ground to hope that cephalic auscultation may become of value in the diagnosis of these diseases.

THE CURABILITY OF TYPHOID FEVER IN THE PRODROMAL STAGE.

At a recent meeting of the Academy of Medicine of Paris (*Bulletin de l'Académie*, January 14, 1883) Dr. Jules Guérin maintained the existence of mild and abortive forms of typhoid fever. The modified typhoid presents symptoms similar to those of the prodromal stage of the disease as usually described, yet is not to be confounded with the prodromal stage. In each case the symptoms observed are the first manifestations of the specific poison. The difference, however, lies in this, that in the one the disease is arrested at this stage owing to an insufficient dose of the virus, in the other the symptoms are due to the first weak efforts of a large dose, and will increase in severity unless the virus be destroyed.

The author thought that the action of the fever-poison might be compared to the action of such a poison, *e.g.*, as arsenic. When a dose of arsenic was taken it produced first, by virtue of its presence in the stomach, a certain local action; but presently, if it was not expelled or neutralized, it became absorbed and gave rise to a general action. So the poison of typhoid fever, when it entered the body, produced a primary local action, and then, becoming absorbed, gave rise to the characteristic train of general symptoms. The poison might be introduced primarily into the lungs through the respiratory passages, into the nervous system by absorption through the skin, or directly into the intestinal tract; and before it became absorbed into the general system it produced in these organs a certain local action, giving rise to symptoms which were truly prodromal. The prodromal symptoms would thus indicate the local action of the fever-poison before its absorption. Guérin further claimed that it was possible in this prodromal stage to eliminate the poison and thus cut short the disease. His plan of treatment was based upon this belief, and consisted in the administration of purgatives or emetics, according as the intestinal or gastric symptoms predominated, at the very earliest possible moment. He then gave charcoal, and continued the administration of evacuates and disinfectants on alternate days, until the patient was cured. Dr. Guérin made the rather broad assertion that, during several years in which he had pursued this plan, he had never had a case terminate fatally.

The author's reasonings seem plausible enough; nevertheless when he asserts the invariable curability of typhoid in its prodromal stage there is room for doubting the accuracy of his diagnostic powers. We have elsewhere heard the question put whether quinine might not avert impending typhoid. But in that instance also, although there seemed abundant evidence to justify an affirmative answer, the question was rightly considered to be still an open one. And so while Guérin's claims certainly deserve to be noticed, we do not feel disposed to accept them as the unquestionable proof of the curability of typhoid fever in the prodromal stage.

THE NEW AQUEDUCT BILL.

Now that a new aqueduct is considered necessary by the politicians at Albany, it is quite important that the expenses for the same should be reduced to a consistent minimum. It will be quite difficult, it is true, to take the huge job entirely from the hands of some of the interested workers. Every movement in that direction, however, deserves the support of tax-payers and the public at large. The new water bill from the anti-Ring association of tax-payers of the city has some very commendable features in it, looking toward the reduction of expenses and the checking of political jobbery. Although the provision for a commission of seven citizens, to be appointed by the Mayor, representing the different senatorial districts of the city, is a wise one in itself, it does not by any means prevent the appointment of incompetent, but influential politicians to such an office. Still, such appointment must necessarily be trusted to His Honor the Mayor. The best safeguard against incompetency on the part of members of the proposed

commission will be guaranteed by their fitness to continue investigations concerning the water supply, and within a given period to present a report, which shall be open to public criticism for a reasonable period. This at least insures, to a certain extent, fair play to all such as are interested in seeing that the work is done properly.

THE NATIONAL BOARD OF HEALTH I

THE lack of support given to this organization by the last Congress is still a matter of warm discussion among our sanitary confrères. Much that was said against the Board in Congress was rhetorical drivel, of which the country should be ashamed. It is very evident, however, that Congress and the commercial interests of the country have not yet been brought to see that preventive medicine as carried out by a national body will be useful and economical. Such being the case, the medical profession is not called upon to start a propaganda in the matter. Another epidemic will be more potent in this direction than tomes of arguments. We believe that a sentiment in favor of a national health organization will again be developed, and that it is only a question of time.

TRICHINA SPIRALIS AND GERMANY.

THE trichina spiralis seems likely to be the cause of international difficulties. The German Government has prohibited the introduction of American pork on the ground that it is infested with trichinæ and therefore dangerous to health. There has not been sufficient examination as yet to determine the exact relative merits of German and American pork, as regards freedom from trichinæ. It seems, however, that the American article is affected to a slightly larger extent than that of Europe. On the other hand, there has as yet been no well authenticated case in which trichinosis in Germany was produced from eating pork imported from America. The prohibition is, we believe, a political rather than a sanitary measure. It is understood that Secretary Frelinghuysen has taken the matter in hand, and if he fails to secure a repeal of the prohibition, will lay the matter before Congress.

THE NEW HOSPITALS FOR CONTAGIOUS DISEASES.

THE hospital for contagious diseases on North Brothers' Island, has been completed and delivered to the sanitary authorities. It has cost \$66,900. A submarine cable of three wires to cost \$900 will soon be laid to Port Morris, when there will be direct telegraph communication between the island and Sanitary Headquarters. In the summer a strong steamboat, to cost \$30,000, will be built to transport patients and employes to and from the hospital. A contract will be awarded to fill in a marsh on the island and build a sea-wall, this will cost \$5,000. Specifications and plans are preparing and bids will be advertised for an administration building to cost \$15,000; a boiler-house and laundry to cost \$15,000; a kitchen building to cost \$8,000; steam-heating apparatus to cost \$10,000, and corridors to connect all the buildings with the hospital to cost \$3,000. The sanitary authorities will also soon advertise for proposals to build, at a cost of \$50,000, the hospital for children sick with contagious diseases at the foot of East Sixteenth Street.

News of the Week.

DEATH OF BARON JULES CLOQUET.—Baron Cloquet, one of the oldest medical men in France, died on February 23d at the age of ninety-four. He was the author of several works on anatomy and surgery. For thirty years his anatomy was a standard work.

A MICRO-ORGANISM FOR YELLOW FEVER.—Peronospora Lutea is the title of the micro-organism which Dr. Carmona del Valle believes to be characteristic of yellow fever. The germs of this cryptogerm are always to be found in the excretions and in the fluids and secretions. Animals inoculated with it show febrile symptoms. After recovery they are not affected by a second inoculation.

THE GRADUATING CLASS at the Miami Medical College numbered forty-one.

THE MICROCOCCUS OF CEREBRO-SPINAL MENINGITIS.—At a meeting of the Berlin Society for Internal Medicine, February 10th, Professor Leyden demonstrated the presence of micrococci in cerebro-spinal meningitis. He referred to the fact that these organisms had been discovered in this disease by Klebs and Ebert. Leyden found them in traumatic meningitis also. He distinguished them from decomposition organisms by their less rapid movement and their shape. He thought that with the present evidence there was no doubt that cerebro-spinal meningitis was a parasitic disease.

IS IT SCIENCE, OR SNOBBERY, OR ONLY GOSSIP?—Our British journalists write that "the auspicious result of the accouchement of H. R. H. the Duchess of Albany, is a source of great pleasure and congratulation. . . . Prior to the happy event there had been some natural anxiety among the many friends of etc., etc." This all sounds very strange in American ears, but American physicians do not have to act as medical valets to a particular class.

THE DETROIT MEDICAL COLLEGE held its annual commencement on February 28th, and graduated thirteen students.

THE MICHIGAN COLLEGE OF MEDICINE held its annual commencement on March 5th, graduating a class of twenty-eight.

THE COLUMBIA VETERINARY COLLEGE AND SCHOOL OF COMPARATIVE MEDICINE, holds its annual Commencement on March 29th.

THE BUFFALO MEDICAL COLLEGE at its last Commencement graduated fifty-seven students. The Faculty has accepted the resignation of Prof. Charles A. Doremus as Professor of Chemistry and Toxicology. Dr. R. A. Witthaus was elected to the vacant chair.

MORE COMMENCEMENTS.—The seventy-sixth Commencement of the Medical Department of the University of Maryland took place, March 15th, at Baltimore. Eighty-seven graduates received diplomas as doctors of medicine and thirty-four as dental surgeons. The annual Commencement of the Woman's Medical College of Pennsylvania was held March 15th. The degree of M.D. was conferred upon thirty-five women.

RETIREMENT OF PROFESSOR MULHERON.—Professor J. J. Mulheron, who has held the Chair of Medicine in the Michigan College of Medicine, recently retired. At the close of his last session the students of the college presented him with a handsomely engrossed address, expressing warm sentiments of regret at the retirement of their teacher, and of acknowledgment of his work. We congratulate the able editor of the *Medical Age* on the fact that he is appreciated.

THE NEXT MEETING OF THE SANITARY COUNCIL OF THE MISSISSIPPI VALLEY will be held at Jackson, Miss., beginning on Tuesday, April 3d, proximo. In view of recent action, legislative and judicial, affecting the sanitary interests of territory not embraced in the Council, in common with the Valley proper, invitations are extended to prominent sanitarians and health officials in the South Atlantic and Gulf States. John H. Raugh, M.D., the Secretary (Springfield, Ill.), should be promptly advised by all accepting invitation.

DEATH OF A LEPROUS PATIENT AT SALEM, MASSACHUSETTS.—Charles D. Erby, a leprous patient at the Salem (Mass.) Almshouse, who contracted the disease in the Sandwich Islands, and whose case has excited much apprehension, died there March 19th.

FIRST REPORT UNDER THE NEW RULE FOR RAILROADS.—The Railroad Commissioners of the State of New York have adopted a requirement to the effect that whenever an accident of any kind occurs on any railroad in the State, the particulars shall be at once telegraphed to them. The first report of the kind was transmitted March 19th, by the New York Central & Hudson River Railroad authorities. Their fast train, which left New York at half-past ten that morning, struck a man south of Yonkers, who was walking on the track. He was found by the side of the track with his right arm and side badly injured, but no bones were broken.

A NEW WATER BILL.—A meeting of representatives from various reform and anti-ring associations was held at the headquarters of the Central Taxpayers' Association on the evening of March 19th. The organizations represented were the New York County Anti-Monopoly League, the Council of Reform, the West Side Association, and the Taxpayers' Central Association. The object of the meeting was to consider the new Water bill, which has been prepared in accordance with the report of the Water Committee. Its principal features are to have the work on the new aqueduct done under the direction of a commission of seven members, one from each Senatorial district, to be appointed by the Mayor, to limit the total cost of increasing the water supply to \$20,000,000, which sum is to include the entire expense of getting land for "right of way," etc. Other provisions of the bill are that there shall be further investigation of the water problem by the commissioners when appointed; that they shall make their report within three months and exhibit the said report for public inspection for one month, and shall also give the citizens a hearing in regard to it, make any necessary modifications and complete the report within one month. The bill will also contain the usual provisions for securing the necessary land by agreement instead of by process of law, arbitration, condemnation, etc.

PROFESSOR ARLT has been given the cross of the order of Francis Joseph in recognition of his long services as a teacher and worker in the Vienna Medical Faculty.

A TRAINING SCHOOL FOR NURSES has been organized in connection with the Cincinnati College of Medicine and Surgery. The first term begins on March 26th.

CANDID CRITICISM ON THE NEW CODE.—In the midst of the flood of vituperation, the charges of dishonesty, greed, avarice, and trickery which have been made against the profession of New York in the name of the Code, it is due that there be an acknowledgment of the candor and fairness shown by the *Weekly Medical Review* and the *Medical Age*. These journals have taken the pains to let their readers see that there are at least two sides to the question.

THE KENTUCKY STATE MEDICAL SOCIETY meets at Louisville on April 4th. Dr. L. S. McMurtry, Secretary.

THE BILL TO CREATE A STATE BOARD OF EXAMINERS.—As widespread as has been the interest excited by the State Society on the position it assumed a year ago on the subject of Medical Ethics, in our opinion, says the *Buffalo Medical and Surgical Journal*, the most vital question presented for the consideration of the society was the recommendation of a bill for the creation of a State Board of Examiners. The proposed bill came before the society in the report of the committee on legislation, and was evidently prepared with great care. It sets forth: 1, what it means to be a practising physician in this State; 2, that after some future time (December, 1883) a person shall not have the right to practise medicine in this State unless licensed by the State Board of Examiners; 3, that candidates for license to practise medicine may select to be examined in any of the schools of practice represented by the incorporated State medical societies; 4, that the records of the examinations upon which licenses are granted shall remain a part of the archives of the University of the State; 5, it repeals all acts or parts of acts authorizing medical colleges or other corporations to grant degrees which shall be licenses to practise medicine.

THE MORPHINE FIEND.—Our readers in the city are warned against a certain woman who is at present visiting physicians' offices and asking for a hypodermic injection of morphine. Her plan is generally to appear to be suffering intensely from neuralgia and to be in a state of pitiable weakness and depression therefrom. She claims to have been sent by some one who has highly recommended the particular medical victim on whom she is calling. After securing a hypodermic injection, she inquires for the toilet room, and having disembarrassed her bladder, she waits a while and then demands another injection. If this is denied her, she sits down refusing to leave, and refusing to pay, claiming that she has not been treated properly. In one case she declared she would stay all night, greatly to the horror of her modest bachelor attendant. The woman in question is about thirty-five years old, and is tolerably well dressed, though rather dirty. She claims to be a little deaf. Quite a number of physicians have already been annoyed and imposed upon by her.

THE NEW YORK COLLEGE OF PHARMACY ALUMNI.—The twelfth annual meeting of the College of Pharmacy Alumni Association was held March 16th, in the college. The following officers were chosen for the ensuing year: *President*, George Inness; *Vice-Presidents*, Charles F. Hubner, A. G. Cook, and Frank Hay; *Secretary*, Frederick Hohenthal; *Treasurer*, L. M. Royce, and *Registrar*, John Oehler. An exhibition was given in honor of the graduating class of '83.

A SCHOOL OF SANITARY ENGINEERING is to be established in connection with Columbia College.

TRAFFIC IN PAUPER BODIES IN MASSACHUSETTS.—Governor Butler has charged that a traffic in pauper bodies has been going on in Massachusetts for many years. It has been recently stated that of 2,800 deaths in ten years 580 bodies were delivered to the medical colleges, according to law. There is no record of the disposition of the remainder. They are supposed to be buried in Potter's field, but it is alleged that some of the graves contain no bodies. Charges have been made that bodies were preserved in a pickling fluid and sent to distant points in kerosene barrels. Country medical colleges, it is well known, are generally supplied from the cities in this way. These colleges need the "material" in question, and under proper restrictions should be allowed to have it.

THE LATE PREMIER GORTSCHAKOFF.—An examination of the intestines of the late Premier Gortschakoff has shown the presence of phosphorus in them. It is suspected that he was poisoned.

DEATH OF DR. C. HENRY KING.—Dr. C. Henry King, School Commissioner of Richmond County and Physician-in-Chief of Sailors' Snug Harbor, died at Quarantine Station, Staten Island, March 18th, of pneumonia. Dr. King was for a long time Physician-in-Chief of the Seamen's Retreat Hospital. He was well known for his energetic advocacy of the physical examination of seamen before shipment.

THE BODIES OF MURDERERS AND THE PREVENTION OF PUBLIC FUNERALS.—The Connecticut Legislature recently passed a bill directing sheriffs to cause the body of any executed criminal to be quietly and decently buried at an expense to the State not exceeding twenty dollars. The sheriff may deliver the body to relatives, still retaining exclusive direction of the funeral, or he may at his discretion refuse to deliver it where there is a prospect of an extravagant and disgraceful exhibition. There is a prospect that some legislation upon this matter will be undertaken by the New York Legislature.

WELL-WATER SUPPLY OF BROOKLYN.—The health authorities of Brooklyn have condemned a large number of wells as containing water unfit to drink.

THE WILL OF SIR THOMAS WATSON.—Our London correspondent writes that Sir Thomas Watson's will has been proved. The personalty alone amounts to more than £164,000. With the exception of a few legacies, this sum is divided between his son and his daughter. Large fortunes—whether acquired by practice or inheritance—are not common amongst medical men in Great Britain. The above amount is certainly large, even for a court physician with an extensive practice and world-wide reputation.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 15, 1883.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE REGULATION AND REPRESSION OF PROSTITUTION.

DR. F. R. STURGIS read a paper on the above subject, in which he made the preliminary statement that although the problem had for a long time been under discussion in different countries, it was yet far from solution. He then discussed the question under three heads: first, the causes of prostitution; second, the necessity of regulating the evil; and third, the results obtained by legislative action in this direction.

With regard to the causes, he had derived his information from three sources—French, English, and American—and after reviewing at some length the works of Sanger, Acton, and others, it was found that all these writers had reached the practical conclusion that man is the aggressive party and is primarily responsible for the existence of the evil.

The next most prominent cause is the desire which women have for dress and luxury, not only for themselves, but for the purpose of attracting and pleasing the opposite sex. The desire for luxury exerts a more potent influence in the higher than in the lower classes. In this country, except among the foreign born, the use of intoxicating drinks enters much less frequently as an assignable cause than in any other country except England.

Another cause to which special attention was directed was the promiscuous herding of people in tenement-houses and the absence of home influence.

The necessity for regulating the evil became especially apparent when its consequences, as shown by communication and propagation of venereal diseases were studied. It was estimated from a calculation based upon Parisian statistics that in the present population of the city of New York there are in round numbers eleven thousand prostitutes; that annually there appear for treatment of venereal diseases in the various public institutions of the city about twelve thousand patients; that in both public and private practice there are probably sixty thousand persons who are being treated for venereal diseases, and that of this number there are probably forty-five or fifty thousand who are syphilitic. When the additional fact is taken into consideration that probably from a third to a half of the syphilitics are really capable of conveying the disease, the necessity for regulating the evil at once became apparent. The women who are most dangerous, so far as syphilis is concerned, are not the old prostitutes who have plied their vocation for years, but the young girls who come upon the town and fall to the lot of the so-called better classes rather than the working-men or the class even lower than those, and this fact, in great part at least, accounts for the larger proportion of cases in which the initial lesion of syphilis, or the chancre, is met with in private practice. It is important that this fact should be recognized among physicians, for the initial sore of syphilis is frequently so slight as not to attract any attention, and the malady goes on unchecked until syphilis is carried into families. The old prostitute has passed beyond the condition most favorable for the propagation of syphilis, while the young woman, who is most attractive, has the disease in its stages most favorable for contamination. The real danger, then, is not so much for the persons who receive the syphilis, because, if then recognized, it is very amenable to treatment, but the penalty falls in full force upon those to whom the disease is transmitted.

Dr. Sturgis then discussed at some length the obstacles met with in all attempts to restrict the evil, such as the natural repugnance of the question, the tender re-

gard for the rights of the subject, and the somewhat prevalent belief that the evil is one which should not be interfered with, but that those who contract the diseases incident thereto should be allowed to suffer, etc.

With reference to results obtained by legislative action in this direction, special reference was made to the decided benefit which had followed the enactment of the English regulations. At the same time it must not be overlooked that if the disease could be confined to house prostitutes, there would be much greater hope of restriction than at present exists. The great difficulty, however, existed in the inability to restrain or check clandestine prostitution. In Paris it is estimated that there is only one inscribed woman to six illegal prostitutes; that is, that the number of those engaged in clandestine prostitution is nearly six times as great as of those who follow it as a business, register, and submit to examination. The French writers on this subject, while admitting the value which is obtained by regulating it, at the same time confess the danger of driving inscribed women into clandestine prostitution, or at least increasing the number of clandestine prostitutes.

The conclusions reached by the speaker were that among the better classes it was impossible to repress prostitution; that at the present time the only hope existed in the ability to regulate it among the lower classes who were found diseased, by sending such persons to hospitals, where they could be compelled to remain until they were either absolutely cured or rendered the least possible innocuous. Any attempt, however, to check the evil must be done without sentiment. If the question became one of mere repression or control, all attempts at repression would be absolute failures; but if an effort were merely made to regulate it, he believed that its regulation could be as easily accomplished in the city of New York as it has been in London and in some other large cities, where most of the women were well known to the police, whether in or out of houses.

Dr. Sturgis then presented an interesting question, namely, the effect which inscription has toward depopulating a country, a fact to which a French writer had directed especial attention. No such result, however, need be feared in this country.

In conclusion he directed attention to the rules laid down at the International Statistical Congress held at St. Petersburg with reference to investigations concerning the existence of syphilis.

The PRESIDENT remarked that no laws were of effect which were in advance of public opinion or were not sustained by public opinion, and that it frequently occurred that laws which had been enacted that were not sustained by public opinion had produced most disastrous results. That there was a moral, social, and political aspect of the question under consideration was apparent. That there was also a legal aspect was equally apparent, and in order that it might be properly presented he had invited Judge JOHN R. BRADY, of the Supreme Court, to be present and participate in the discussion, and he then introduced the honored guest to the Academy, who first referred to the study of this subject as presented by certain English writers, and in all of their articles one remarkable feature was noticeable, viz., that none of them had reached any conclusion. The Judge, from his general consideration of the subject, thought that the better opinion of the community at large seemed to be in favor of legislative enactment, yet he doubted very much indeed whether such enactments could be secured at the present time. The judiciary had always been arrayed against prostitution in any form, and just here he took issue with Dr. Sturgis, and said that a woman has not control over her own body; that, according to the law of the State of New York, she can be arrested as a vagrant and sent to the penitentiary if it can be proven that she is without other support than that derived from prostitution. The difficulty, however, in enforcing all existing laws with reference to prostitution was the migratory character of

the persons engaged; that is, when routed from one street they would migrate to another, and so move on to different points, and thus manage to evade the law. With reference to clandestine prostitution, it seemed impossible to reach it in any way. His conclusion was that no reform can ever be accomplished except through the instrumentality of the medical profession; that if the efforts of medical men were sufficiently persistent to give rise to the proper sentiment in the community, all the social and intellectual objections which had heretofore been raised against interference with this evil might be waived, and the people might say we will abide by your opinions concerning this known evil, and will unite with you in all reasonable efforts for either its regulation or its repression. Until such a sentiment can be created all efforts at securing legislative enactment would very probably be unavailing.

DR. STURGIS then read a letter received from Dr. A. P. Gihon, of the United States Navy, expressing his great regret at being unable, on account of extreme sickness in his family, to be present and participate in the discussion, and also expressing the view that the question under consideration was one which must be met by physicians and looked squarely in the face, and that whatever relief should come to the community must come very largely through the united efforts of the medical profession.

DR. L. WEBER remarked that three modes of dealing with the question of prostitution had been put into application in various countries. First, to do nothing concerning the evil; second, to adopt the policy of repression, which had been applied in Rome, Spain, Bavaria, and Austria; and, third, to recognize the evil and attempt forcible regulation. All of these methods had proved failures. He believed that the evils of prostitution could be best restricted by turning attention directly toward the means best adapted to diminish the propagation of syphilis. First, syphilis must be recognized; second, it must be treated with energy; third, greater hospital facilities than now exist should be afforded for the treatment of syphilitic persons.

DR. R. W. TAYLOR believed that so far as legislation is concerned no benefit would be derived in that direction from efforts to restrict the evil or its consequences. Reform, if any, must come from two sources: First, in a manufactured sentiment, which had already been alluded to by Judge Brady, and which must come largely through the medical profession; second, in the better education of the profession itself concerning venereal disease in all its phases. The profession should to a man be educated up to a point of being able to recognize syphilis under whatever phase it might appear. Gonorrhœa and chancroid are of such common occurrence that they might be said to be endemic, even in polite society, and the difficulties in the way of their recognition were manifestly less than concerning syphilis. He believed if the fact was thoroughly understood that syphilis is eminently a curable disease, and if every medical man was able to recognize the disease in all its phases, that the evil consequences attending its existence and its propagation might be very largely restricted, and, so far, one of the necessities of restricting prostitution could be met.

The discussion was closed by Dr. Sturgis, who referred to the great difficulty in educating the people up to the point of regulation or repression of the evil.

The Secretary then read a letter from Dr. Willard Parker, gratefully acknowledging the kind expression of sympathy extended to him by the President of the Academy in his inaugural address, and conveyed by the Committee, consisting of Drs. Detmold, Adams, and Hubbard.

The Academy then adjourned.

THE USE OF THE OPHTHALMOSCOPE.—Nothnagel says that no physician should be allowed to practice who does not know how to use the ophthalmoscope.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 28, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. BEVERLEY LIVINGSTON presented specimens with the following history:

DOUBLE HYDRONEPHROSIS DUE TO ABNORMAL BENDING OF THE URETERS—SUPPURATIVE DISEASE OF THE KNEE-JOINT—ABSCESS OF THE LIVER.

"Thomas M— was delivered by forceps in the Nursery and Child's Hospital September 29, 1882, of a healthy mother, and the mother and child did well. nothing being noticed until November 1st, when the nurse reported that the child's left knee was swollen, red, and painful, and that she thought the mother had turned over on the child in her sleep and so injured it, but the mother claimed the knee had been swollen since birth. On examination the knee-joint presented the signs of an acute inflammation, being red, swollen, and painful on pressure, and the femur seemed to be dislocated inward, also the lower end of the femur and the upper end of the tibia seemed enlarged. Fluctuation was very apparent, and this tumor evidently communicated with one in the lower and outer part of the thigh. An opening was made, a quantity of pus let out, and a drainage-tube inserted. Dead bone was found at the bottom of the cavity. The limb was dressed once a day. The temperature was normal before the operation, but it went up to 102° to 103° F. afterward, with a rapid pulse, and in five days (November 6th) the child died, having had vomiting and diarrhœa for the last two days of its life.

"The autopsy was made November 7, 1882. The body was emaciated, there was an opening on the under and outer surface of the left thigh just above the knee-joint; the knee was enlarged and the femur seemed to be dislocated inward. On dissection the abscess was found to extend upward on the under and outer part of the thigh more than half the length of the femur, and in it a piece of drainage-tube was found. This abscess communicated with the knee-joint. The external condyle was necrosed and thus allowed the femur to slip inward. On section the shaft of the femur was found to consist of two layers of bone, the outer being of a different structure from the inner, denser and showing striations in the opposite direction, and was evidently due to the inflammation of the periosteum. Also there seemed to be a line between the normal shaft of the bone and this outer layer. The lines of ossification at the end of the femur were normal and the ossification of the other bones was also normal. The lungs showed catarrhal pneumonia in the posterior part of both. The heart was normal. The liver contained two abscesses in the middle of the right lobe, about three-fourths of an inch in diameter. The spleen was normal. Kidneys: They were both removed before they were examined. The right one was opened and the pelvis found to be considerably dilated, with atrophy of the pyramids, only the cortex remaining. The left was in the same condition. The pelvis of both kidneys contained a small quantity of urine, no renal calculi could be found. The part of the ureters that had been left in the body was normal in size and entered the bladder naturally, and the bladder was normal as well as the urethra. The cause of the hydronephrosis seemed to be the bending of the ureters twice on themselves. On the left side there was also constriction at the second curve."

DR. ROBERT NEWMAN presented a specimen of

CARCINOMA OF THE RECTUM,

accompanied by the following history: Mrs. S. D—, aged fifty-six; widow; three miscarriages; no living children; menstruated at fifteen; regular throughout until menopause.

Family history.—Father died at age of seventy-eight—cause, dropsy; mother died at age of seventy-two—cause,

senile asthenia. Had four brothers and four sisters, of which one brother and one sister died in childhood (seven and nine years of age). The rest are living and well.

Personal history.—The patient had most of the diseases of childhood. At twenty years of age she had a severe attack of dysentery, which came on after a miscarriage and lasted nine weeks. Since that time she was troubled with more or less dysentery every summer. Three years ago she was attacked by erysipelas of the face and head which lasted two months. One year ago she had an attack of spasmodic asthma, from which she suffered for about two months. The present complaint showed itself about two years ago, with pain in lower part of abdomen, and occasional bloody stools and the passage of "flesh-like" matter from the bowel, which had a very bad odor, her underclothing also was continually stained by matter. This lasted about one year. In August last she first noticed a lump at the anus, of about the size of a chestnut, which rapidly enlarged, was exquisitely painful, especially during the act of defecation, and a larger amount of bloody, bad-smelling matter was continually discharging from the bowel. One night in bed she felt the sensation at the anus as if a pin concealed in the bed-clothing had pierced her. On feeling with her hand, she discovered what she thought to be the point of a needle protruding partially at the side of the anus; pulling it out, however, and looking at it, she discovered the offending article to be a sharply pointed fish-bone, about one inch in length. She thinks it was a part of the backbone of a cod. This happened on New Year's day last.

January 8th.—Patient first presented herself at the Northwestern Dispensary, complaining of piles, with passage of blood and a continuous discharge of matter, constipation, etc. An examination was refused by the patient at the time, but a promise was given to return and allow it. Was given a powder to do away with her constipation.

January 10th.—Patient presented herself for examination, though she thought the powder had given her some relief. Examination revealed a tumor protruding from the bowel of about half the size of a hen's egg, which had at a superficial glance, somewhat the look of a bunch of protruding hemorrhoids, beginning superficially to ulcerate. To the touch, however, the tumor had a peculiarly hard feel, and digital examination revealed that for about three inches (in fact as high as the finger could reach) the rectum was constricted and band-like rugæ, hard as cicatricial tissue, were felt in every direction. This peculiar hardness and ready bleeding of the protruded mass (which also involved quite a considerable portion of the ring of the anus) coupled with the age of the patient and peculiar haggard and distressed look, led to the diagnosis of carcinoma of the rectum. As the woman was perfectly willing to undergo an operation for the relief of her distressing symptoms, and the facilities of the dispensary did not allow of the operation being performed at the latter place, arrangements were made to operate at her own residence with the galvano-cautery.

Operation. January 27, 1883, by galvano-cautery knife, assisted by Drs. G. Meier and Bassett.

The operation was performed for two reasons: first, to give relief to the patient because the growth had occluded the rectum; and, second, to determine the nature of the disease. The operation was performed with the galvano-cautery, the growth being pierced with a double thread, which placed it under the control of the operator. Dr. Newman preferred this method to seizing the tumor with the forceps or other instruments, for the reason that in this way hemorrhage was avoided, as these growths are sometimes very brittle and very vascular. The result of the operation had been that the outside appearance was very much improved, but that the growths above in the rectum had become aggravated. The specimen was referred to the Committee on Microscopy.

CARCINOMA OF THE BREAST.

DR. NEWMAN also presented a specimen with the following history: On February 18, 1882, he presented to the Society, in behalf of Dr. Rodenstein, a specimen which he supposed was one of carcinoma of the breast. It was referred to the Committee on Microscopy, which reported in April, 1882, that the specimen consisted simply of inflammatory tissue, that it contained no true glandular tissue, and exhibited nothing which suggested the existence of malignant disease. In less than a year, however, the disease returned. The original tumor was in the left breast, involving the gland itself. The nodule which reappeared was not in the cicatricial tissue, but closely above it and a little toward the axilla. It was removed on January 16, 1883, by Dr. Rodenstein, Dr. Newman assisting. The specimen was referred to the Committee on Microscopy.

DR. WYETH asked Dr. Newman what relation he supposed the fish-bone had to the carcinoma of the rectum in his first case.

DR. NEWMAN believed that it was the exciting cause, and further, that most carcinomatous growths could be referred to actual injury of some kind. He did not accept, to very much extent, the theory of inheritance, and believed that cancer was in most instances caused by some local irritation or injury.

WAXY DEGENERATION OF THE PLACENTA.

DR. TAUSZKY presented a specimen with the following history: A primiparous woman, twenty-one years of age, had a miscarriage on May 22, 1882. She again became pregnant, and under his care exercised all possible precautions to prevent a second abortion or miscarriage, but despite all means employed, premature labor came on at the end of the eighth month, and after a few hours the woman gave birth to a child which, although very feeble, was still living. Dr. Tauszky was unable to find any cause for the premature labor, unless it existed in the condition of the placenta, in which he found certain changes. There were nodules of different sizes, yellowish and grayish in appearance on the decidua surface, but none upon the amniotic surface. These nodules varied in size, from that of a pea to a walnut, and were very numerous. The placenta presented the gross appearances of what is ordinarily known as fatty degeneration. He remembered that Dr. Green, in Dr. Heitzman's laboratory, had examined several of these specimens, and reached the conclusion that they were the seat of waxy instead of fatty degeneration, and he presented the specimen on that account. He was unable to find any disease whatever which could explain the occurrence of the change in the placenta, or the premature birth. Another point of interest was the fact, that on July 8th, after the occurrence of the miscarriage in May, the woman thought that she conceived, and she had not menstruated after the occurrence of the miscarriage. Dr. Tauszky believed that this case was evidence in support of the opinion which he had long entertained, that menstruation and ovulation are independent of each other entirely. The specimen was referred to the Committee on Microscopy.

MEDULLARY CANCER OF THE STOMACH—PATIENT WITH GOOD APPETITE.

DR. HEINEMAN presented a specimen accompanied by the following history. An interesting feature in the clinical history of the case was the fact that the patient continued to have so good an appetite up to one or two days previous to his death.

"Vogel B.—, sixty-three years of age; Austrian; single, and without occupation, was admitted to Mount Sinai Hospital, January 21, 1883. His family history was negative. There was no history of alcohol, rheumatism, or syphilis. The patient was well up to two years ago, when he began to have epigastric pain, increased after eating. The pain has increased in severity, and referred to the vertebral column for a time, and has been severe

enough to keep him from sleeping. He has never vomited and his appetite has remained good.

For six months he has passed a large quantity of urine. Upon admission, patient was poorly nourished, and jaundiced. His appetite was good, but he took very little food because of the pain it caused. The bowels were constipated. On examination a hard resisting mass was felt in the epigastric region, reaching in the median line down to within a half inch of the umbilicus, and extending on the left side to the free border of the ribs. The urine had a specific gravity of 1.022, was acid, contained thirty-three per cent. of albumen, and the quantity passed was thirty-eight ounces in twenty-four hours.

After admission the pain increased, but was subdued with morphine, and without vomiting the patient rapidly lost strength and died February 16, 1883.

Autopsy.—The brain was not examined. The heart contained post-mortem clots. The mitral valves were thickened. The lungs were congested and oedematous. The stomach: The mucous membrane throughout the posterior and lower half of the anterior walls of the greater and lesser curvatures from the cardiac to the pyloric extremities, was replaced by irregular, flattened, projecting (cauliflower) cancerous masses, which involved the entire thickness of the stomach, had ulcerated through the peritoneal coat in numerous places, projecting beyond, and at these situations had constructed adhesions with the surrounding viscera, thus preventing extravasation of stomach contents. The pancreas was also involved to a considerable extent by continuity of growth. The liver contained a few very small secondary nodules in the right lobe; the left lobe being invaded by continuity of the cancerous growth from the stomach. The kidneys presented the lesions of chronic diffuse nephritis, being increased in size and containing numerous small cysts. The spleen was considerably increased in size.

DR. WENDT referred to a similar case which came under his observation, in which almost the entire cavity of the stomach was occupied by the cancerous growth, and in that instance the singular feature was that the patient had a good appetite up to within two weeks of his death, and was able to take a very large amount of food, a fact difficult to be explained by the size of the cavity found at the autopsy. Vomiting occurred for only about one week before the patient's death, and yet the cancer was present probably a year previously.

(To be continued.)

ASAFOETIDA IN THE TREATMENT OF ABORTION.—In the *Journal de Médecine de Paris* of December 16, 1882, are collected the results obtained by several observers in the prevention of abortion and premature labor by asafœtida. Dr. Laferla, acting upon the theory that the death of the fœtus was owing to an asthenic condition of the uterus, administered the drug in a number of instances. In nearly ninety per cent. of the cases so treated, the patients (who had aborted from two to five times in former pregnancies) went on to full term. Drs. Giordano and Carzani announce equally favorable results, though the number of their cases was smaller. The latter prescribes the drug in pill form in doses of one and a half grain twice a day, gradually increased to twelve grains per diem. Dr. Gourgnès recommends the administration of asafœtida, in emulsion with the yolk of an egg, by the rectum.

THE BROMIDE OF ARSENIC IN DIABETES.—Dr. Békai, of Buda-Pesth, reports two cases of diabetes in which Clemens' liquor arsenici bromati was used. In the first case, after eleven days' use of the drug, together with an animal diet, the sugar disappeared from the urine. Upon leaving off the treatment, one per cent. of sugar appeared again, but disappeared upon renewal of treatment. In the second case the results were not quite so good.—*Wiener Med. Blätter.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LONDON COLLEGE OF PHYSICIANS AND MEDICAL ADVERTISING—THE LONDON HOSPITAL AND MEDICAL COLLEGE—PAPERS ON SCURVY AT THE MEDICO-CHIRURGICAL SOCIETY.

LONDON, March 3, 1883.

IN my last letter I referred to the position taken up by the London College of Physicians toward professional advertising in the lay press. The question has now assumed a somewhat different phase. The college has condemned one of its fellows for advertising a lunatic asylum—not in lay journals, but in *strictly professional media*. With a lamb-like docility the fellow in question has submitted and engaged to desist from such objectionable practices in future. The college will doubtless next require its fellows and members to desist from the use of door-plates and to have their names removed from the "Medical Directory." Publicity even of the most respectable kind is apparently objectionable to the sages of Pall Mall. That is, of course, as regards other people, for the officials have no objection whatever to being advertised themselves.

Dr. Mathews Duncan's lectures on "The Sterility of Women" have been recently advertised in a prominent place in *The Times*. What useful purpose can this serve? Only medical men are admitted to hear the lectures at the College of Physicians. This immodest proceeding may perhaps bring a few patients to Dr. Duncan, especially when bulletins signed by him and faithfully chronicling the progress of the Duchess of Albany's accouchement are being simultaneously published in the daily papers. This, however, is venial—nay, even commendable—compared to the advertising of a lunatic asylum in a medical journal!

Such is the stand made by the London College of Physicians. It is scarcely conceivable that a public body, of which Sir William Jenner is the head, should be so unreasonable and inconsistent. The college, however, has never studied the interests of the profession at large. Many of its members have been excluded from the fellowship, not because they are not worthy of it, but for private and personal prejudices. On the contrary, many have been elected who have little or nothing to recommend them except large fortunes or perhaps friends on the council.

The college is, in fact, a club, and that of a very close kind. A letter has lately appeared in *The Lancet*, suggesting that it should be turned into a *bona fide* club and refreshments served. No doubt the Mrs. Grundies of Pall Mall have been holding up their hands in pious horror at this proposal. Yet, if not, why not?

The London Hospital is about to erect a building to serve as a residential college for its students. When erected, this will doubtless prove a considerable attraction to many intending students, as the neighborhood of the hospital is not a nice one wherein to live in lodgings. It is a strange fact that although we have eleven Schools of Medicine in London, only two of them, viz., Kings College and St. Bartholomew's Hospitals, have, I believe, any residential chambers in connection with them.

At the last meeting of the Medico-Chirurgical Society two interesting papers were read by Mr. W. H. Neale and Dr. Hale White, respectively, on scurvy. Mr. Neale (surgeon to the late Eira Arctic expedition) contended that lime-juice may be dispensed with if fresh meat can be obtained. He recommended that the crews in Arctic expeditions should pass the winter in huts on shore rather than on board ship. For food a good deal of fresh flesh meat was desirable. This should be stewed and the blood of the animals should be added to the stew. Preserved vegetables should be mixed with every meal—

not because they possessed any special antiscorbutic properties, but to assist the digestion of the meat.

Dr. White read the notes of a case of scurvy with retinal hemorrhages and dilatation of the heart. Dr. White said there was no previous record of such a condition of the heart in scurvy. The patient had previously suffered from dysentery, which Dr. White considered aggravated the scurvy, the severity of the latter being evidenced by the marked blood-changes.

An interesting discussion followed, in which several veteran naval surgeons with Arctic experience took part. Many of these corroborated Mr. Neale in his statements as to the value of fresh meat.

INEBRIETY AND THE TEETH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a paragraph with this heading you refer to the experience of a clergyman, who thinks he has seen less drunkenness in cases where the teeth have been treated and properly cared for.

This is the recognition of a fact which appears very often in the history of cases of inebriety, namely, the presence of distinct physical causes which are both exciting and predisposing in every case. As, for instance, a man of eminence will invariably drink to intoxication, after a hearty dinner at midnight. Avoiding this, he is abstinent and can fully control himself. A business man never uses spirits to excess, except when he sits up all night or travels by rail. After this exposure he is powerless to stop short of profound intoxication. With proper rest every night he can be a thorough temperance man. A broker was forced to retire from business because of excessive use of spirits. He was able to fully abstain as a manufacturer in a quiet town. Every time he went back to Wall Street, even for a few hours, he drank, although not tempted in any way more than others.

In the *Journal of Inebriety*, vol. ii., Dr. Harman, of Ohio, reports a case of a pronounced inebriate who recovered, and remained a sober man ever after, dating from the expulsion of a tape-worm. An officer in the late war, who was considered a chronic inebriate, dating from a wound of the tibia, recovered immediately after the removal of some dead bone and the healing of the wound. He had tried repeatedly before to abstain, but failed. The recovery after the operation was in circumstances more adverse than ever before. The late Dr. March, of Albany, trephined the skull of a man who had drank to great excess, from the time of an injury by a fall on the head. The man recovered and never used spirits after, for a period of eight years, up to his death.

In an article in the *Chicago Medical Journal* for November, 1881, I have stated many of these singular cases, where injury and irritation of any part of the body may react by some unknown law and develop inebriety. In many of the cases which come under my care there is often apparently very insignificant states of the body, which are found to be prominent in the causation—sources of irritation and exhaustion, neuralgias, nutrient disturbances, and local derangements of almost every description, the removal of which is followed by a rapid cessation of the desire for drink, and the cure of inebriety.

The teeth may very naturally be sources of irritation, which, if it does not cause inebriety, will most naturally keep up the irritation which provokes a continuance of this disorder.

In the majority of these cases a special diathesis may be the favoring soil, which will develop inebriety from the slightest causes. A neurasthenic state and general nerve instability, for which alcohol is a most seductive sedative, and inebriety follows with great certainty.

It is only a rational expectation to find that decayed teeth was an exciting cause, and inebriety would be more manageable when this source of irritation was removed. Recovery cannot be expected until all sources of irrita-

tion can be more or less removed. The clergyman who insisted on the care and treatment of the teeth in inebriety as a part of the treatment, was following the teachings of the most advanced science of to-day. If, in addition, nutrition, surroundings, and the removal of all exciting causes was made a part of the treatment, recovery would be the rule and failure the exception. Inebriety is always the result of physical conditions, whether understood or not. The sooner this is recognized and practical treatment based on it, the whole subject will be raised from the realm of superstition and quackery.

The curability of inebriety by physical means and remedies is as practical and real as that of any other disorder. What is wanted is a thorough study of the subject from the standpoint of science, above all theories and dogmas of to-day.

T. O. CROTHERS, M.D.

HARTFORD, CONN.

New Instruments.

A NEW

ADJUSTABLE UNIVERSAL JOINT OR COMPOUND RACKET,

AND ITS RELATIONS TO SURGICAL MECHANICS.

By CHARLES F. STILLMAN, M.D.,

ADJUNCT PROFESSOR OF ORTHOPEDIC SURGERY IN THE NEW YORK POLYCLINIC.

In surgical mechanics we have often been at a loss for a compact joint-racket which would admit of movement in several directions at the same time, or movement in one or two directions and fixation in the others, or an adjustable fixation in all. The racket which is depicted in Fig. A, 1, 2, and 3, is the result of my study to supply

Fig. A.

this want. It is simple and compact, and will admit of motion or fixation at any angle. In its modifications it affords us a means for controlling every twist and deformity to which the human frame is subject, so far as they can be overcome by mechanical methods. This may seem a broad ground to assume, but a few moments' attention to the matter will afford proof of the assertion.

Is there any position of a limb or joint which a ball and socket-joint cannot be made to assume? It is a universal joint, and of course is movable and, if provided with a clamp, adjustable in any direction. A universal movement, so far as its relation to the mechanism of the human frame is concerned, consists of abduction and adduction, flexion or extension and rotation (or, in other words, eversion and inversion).

These comprise the sum total of directions in the movement, and are attainable by the ball and socket-joint.

But suppose we desire to allow motion in any two of these directions and prevent it in the third. This the ball and socket-joint does not allow us to do, its action is either to prevent all or allow all.

It is then of paramount importance to possess a racket or regulating clamp, which will allow one movement to be prevented and the other two allowed, or two prevented and one allowed, or all three prevented or all three allowed, in other words, to possess complete control of movement in all directions.

By placing the racket, just shown, in three different directions, we obtain this complete control, and by placing them opposite a joint, we obtain mechanical control

of the joint; by placing them along the course of a limb we obtain control of the twists and bends of the limb (if controllable); and placed along the trunk or any other part of the body, gives us control of the part, provided, of course, that the attachments of the splint in which the rackets are introduced conform to the proper mechanical laws governing such attachments.

Fig. B.

Fig. B shows how these movements may be applied to a splint for the knee, so far as indicating the relative directions in which the rackets are placed to produce the universal joint; A indicating the position in which the racket is placed to produce movable or immovable abduction or adduction; B, indicating the racket for flexion, and C for rotation. The rackets are operated by a simple wrench which either tightens or loosens them as desired, and they can be readily and inexpensively inserted into any form of apparatus, and the elaboration of this racket into its various applications, which will be fully explained in the future, constitutes in part the ground-work of an improved system of treatment for deformities and diseases of joints.

VENTRAL HERNIA.—Dr. Jordan reports (*Birmingham Medical Review*, February, 1883) a somewhat remarkable case of true and strangulated ventral hernia. The patient was a lady, of previously good health, who, when first seen by Dr. Jordan, had had symptoms of intestinal obstruction for forty-eight hours. All the ordinary sites of hernia were in a natural state. Nothing like hernia was anywhere visible or to be felt, but when the abdominal surface was examined, the lady complained of a tender spot between the umbilicus and the groin—well removed from the inguinal canal. On closer examination a certain fulness was found, not visible to the eye, but clearly different from the corresponding spot on the other side of the middle line. It was decided that he should operate, and there was found a very flat hernial sac containing some eight inches of bowel, the neck of the sac apparently passing through the lower part of the linea semi-lunaris below and to the right of the navel. The lady made a favorable recovery. The dressing at first was a soft new sponge kept constantly moist with a solution of carbolic acid in water and glycerine.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 10, 1883, to March 17, 1883.

BROWN, HARVEY E., Major and Surgeon. Temporarily assigned to duty at Mount Vernon Barracks, Alabama, during the absence on leave of Captain T. A. Cunningham. S. O. 17, par. 2, Department of the South, March 6, 1883.

WILLIAMS, J. W., Major and Surgeon. Upon being relieved from duty at Fort Cœur d'Alène, Idaho, will proceed to Fort Walla Walla, Washington Territory, and report for duty as medical officer of that post. S. O. 24, par. 5, Department of the Columbia, March 1, 1883.

CUNNINGHAM, T. A., Captain and Surgeon. Granted leave of absence for twenty days, to take effect from the 21st instant. S. O. 17, par. 1, Department of the South, March 6, 1883.

HEIZMANN, CHAS. L., Captain and Surgeon. To be relieved from duty in the Department of the South, and assigned to duty at Columbus Barracks, Ohio. S. O. 58, par. 8, A. G. O., March 12, 1883.

TAYLOR, B. D., Captain and Assistant Surgeon. To be relieved from duty at Fort Ringgold, Texas, and will so soon as able report to the Commanding Officer, Fort Clark, Texas, for duty. S. O. 25, par. 6, Department of Texas, March 9, 1883.

WOOD, MARSHALL, Captain and Surgeon. Is assigned to duty at Fort Cœur d'Alène, Idaho. S. O. 24, par. 5, Department of the Columbia, March 1, 1883.

BRECHEMIN, LOUIS, First Lieutenant and Assistant Surgeon. To proceed to Fort Brady, Michigan, and report to the Commanding Officer for duty at that post. S. O. 41, par. 1, Department of the South, March 14, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 17, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
March 10, 1883	0	13	108	4	109	40	0	0
March 17, 1883	0	11	111	4	96	50	2	0

THE RECOGNITION OF MICROCOCCI.—We have received from Dr. Rollin R. Gregg, of Buffalo, a lengthy article on this subject, in answer to the last one by Dr. Geo. A. Sternberg, in which it is reasserted with emphasis that the bacterists never have made proper allowance for the granules and fibrils of fibrin in and about diphtheritic exudations; and in which it is claimed that besides said forms of fibrin there are thousands upon thousands of the granules of decolorized and broken blood-corpuscles, mingled in said exudation, which are also very similar in appearance to micrococci; but which have never before received the slightest recognition. This subject, however, has not that general interest of more practical questions, and because of this and the crowded state of our columns, we cannot spare the space to Dr. Gregg's communication.

MORE ABOUT BORO-GLYCERIDE.—Additional experiments, as communicated to the French Academy of Sciences, appear to show the effective value of M. Le Bon's new antiseptics, the glyceroborates of calcium and sodium. Both of these compounds prove to possess the important advantages of being very soluble, destitute of odor and free from all toxic action; when exposed to the air they both deliquesce with great rapidity, absorbing from the air an equivalent weight of moisture. Both alcohol and water dissolve twice their own weight of the solution. The most effective, in a therapeutic point of view, appears to be the calcic salt; it is said to be absolutely innocuous, and can be applied in strong solution to so delicate an organ as the eye without bad results. In a hygienic sense, both can be employed with advantage as disinfectants, and it is believed that both of the salts will also prove very useful as antiseptics in dressing wounds.

MEDICAL MISSIONARIES.—The Rev. Dr. J. M. Scudder, of Vellore, India, wishes that every missionary in that land were a medical man, and urges the home societies not to send out any workers who have not, at least, a slight knowledge of medicine. He visited two towns for several years in succession without gaining the least hold, apparently, upon the people, when a slight surgical service on his part opened both their hearts and homes. It also opened his eyes to the value of medical knowledge.

THE DANGERS OF CONVALLARIA MAIALIS.—Dr. F. B. Robinson, of Grand Rapids, Wis., reports to us the results of some experiments with the fluid extract of convallaria upon two five-months kittens. Hypodermic injections of fifteen drops in one case and eight drops in the other caused death. Dr. Robinson argues that therefore the drug is dangerous to man—which is hardly a logical inference.

A MOTH IN THE EAR.—Dr. Howard Jones, of Circleville, Ohio, relates the following somewhat dramatic case, *a propos* of foreign bodies in the auditory meatus: "Two gentlemen were walking leisurely down the street a quiet evening in July, after the street lamps had been lighted, one of them wearing a white straw hat. As they came near a gas-post, an insect flying rapidly, struck the straw hat of No. 1, and carromed directly into the right external meatus of No. 2. The gentleman clapped his hand to his ear and screamed with pain. He entered the nearest dwelling, where I found him a few moments later, greatly excited and suffering intensely. The lady of the house had attempted to pour milk into the ear, but could not succeed. Upon examination I discovered the external canal completely plugged with a dirty gray body, which when touched, the patient said, scratched terribly. The blades of a pair of small forceps were at once carefully inserted upon either side and then closed upon the object. By careful pulling, it was gradually withdrawn, and proved to be a gray-and-white moth, something over an inch in length, and so large in diameter that it fitted tightly into the canal."

DEATH OF DR. JOHN H. SAUNDERS.—Dr. Saunders, of Belfast, Me., died at his home on February 24th, at the age of sixty-two. He was a graduate of the New York University Medical College. He had attained a wide reputation as a physician, and was highly esteemed by every one.

ANATOMICAL AND PHYSIOLOGICAL STUDY IN EUROPE AND AMERICA.—A writer in the *Journal of Comparative Medicine*, says: "Among somewhat over three hundred contributions to anatomy and physiology made during the past year, I find the authors distributed as follows: Germans, 160; French, 70; British, 26; Italian, 24; American, 14; Scandinavian, 13; Russian, 6. Among the contributors to physiology, America ranks as one of the last. It will be seen that over half of all the work has been done in Germany.

HOW TO PURIFY THE AIR OF THE SICK-ROOM.—An article on the above subject contained in the *Sanitarian*, March 1, 1883, concludes as follows: "1. To purify the air in the sick-room, place in the bed a small basket or other porous article, containing wood charcoal, for the purpose of absorbing the foul air which, if diffused throughout the surrounding atmosphere, would be constantly returned to the lungs and cause the patient to die of auto-infection. 2. In a sick-room in which infants are sleeping, it is necessary to put a box or basket containing a piece of quick-lime and some wood charcoal, for the purpose of fixing the carbonic acid exhaled from the lungs, and of absorbing all the foul air generated in the system, and given off by exhalation from the skin or otherwise."

A BUSY DOCTOR sent in a certificate of death, the other day, and accidentally signed his name in the space for "cause of death." The registrar says he wishes the profession would be as accurate generally.

PHYSICIANS' PRESCRIPTIONS.—In France it has recently been decided that pharmacists who furnish poisonous medicines on physicians' prescriptions must register the prescription, and also the name of the person to whom the medicine is dispensed. Against this latter regulation serious objection is made, as persons suffering from venereal diseases sometimes do not desire to have such semi-publicity given to their troubles.

MONTHLY ENGAGEMENT CARDS, which may be made useful to the physician, are published by George B. Hurd & Co., of this city. These cards are printed on both sides; the one spaced for recording engagements for three weeks, and the other, one week, and a summary for the month, and are contained in neat Russia, plush, and calf frames.

THE STRUGGLE FOR A LIVING.—We quote the following from a presidential address to the Maine Medical Association by the late William Warren Greene, M.D.:

"Witness the large number of doctors in every city struggling for a mere existence, and see how few out of the whole number really do the work. See how in almost every country village a full practice for one or two good men is piece-mealed by sharp and often acrimonious competition to the detriment of all.

"It would seem that in a calling so high, so noble, so sacred, men fit for such ministry should be sought for; but the great question of the young graduate is not 'Who wants me?' but 'Who will employ me?' not 'Who needs me?' but 'Where can I get a living?' In the case of four physicians dying, each in a country village, during the last year, I am credibly informed that in one instance two, in another three, in the third five, and in the fourth case seven new men came to look the field over within ten days after the doctors' death, sometimes before the burial. In one case two attended the funeral, and in another the widow had three letters from aspirants for the vacant place while the dead body of her husband still lay in the house.

"It is a hackneyed saying, with which too many ears are tickled, that 'there is always room for good men.' Applied to the present condition of our profession it is false. Were only good men and the best men admitted it would undoubtedly be true. But all over the land, in city and country, are well-educated, cultured gentlemen, honest and loyal, striving in vain to secure a competence—yes, a bare living even—and too often is disappointment mingled with shame and mortification at the success of ignorant and unprincipled rivals. I have said that the evil results of this excess in numbers are manifold. It leads to over-practice and to bad practice. The man who is hard pushed, who has few patients and needs more, is tempted to make much of little; to magnify the importance of his cases, both in his own mind and to his patrons: to make uncalled-for visits, and to give too

much medicine ; and unnecessary medication soon ceases to be rational. Patients are injured in mind and body. The community is injured by teaching the people to attach undue importance to trivial diseases, and to overestimate the value of treatment therein. Legitimate, honest practice suffers in reputation ; money is obtained under false pretences."

MEDICAL STUDENTS IN ENGLAND.—The number of medical students officially registered in Great Britain during the year 1882 was, we find, 1,862 ; of these, 1,064 were registered in England, 585 in Scotland, and 424 in Ireland. These numbers are considerably less than those registered as in course of study during either of the three preceding years, the falling off being exclusively in England and Ireland. Two hundred and fourteen fewer students were registered this year in England than last, and one hundred and sixteen fewer students in Ireland. There was no falling off in Scotland.

THE EFFECT OF WORKING IN TOBACCO FACTORIES UPON MENSTRUATION, PREGNANCY, AND LACTATION.—Since it has been observed that tobacco, and especially nicotine, increases the peristaltic movements of the intestines, some have supposed that it would have a similar effect in stimulating the muscular fibres of the uterus. So much has been said on this subject that the French Minister of Finance requested certain physicians to report as to the health of women employed in various tobacco manufacturing houses. These reports have now been received, and the writers are unanimous in concluding that no evil effects upon the sexual organs can be ascribed to the tobacco. The abortions recorded, the deaths of infants registered, and the anomalies of menstruation noticed amongst women employed in tobacco works could be accounted for by causes outside of their employment.—*Lancet*.

HOMŒOPATHY IN ENGLAND.—A homœopathic directory has recently been published in Great Britain. According to its pages there are 260 practitioners of this class in Great Britain and Ireland, four only being in the latter country. As there are 19,947 regular physicians, the ratio of homœopaths to regulars is for England and Wales 1 to 64 ; for Scotland, 1 to 170 ; and for Ireland, 1 to 609. Most of the homœopaths are in large towns ; thus London has 85, and Liverpool 11. The contrast between the condition of things, as shown above, in England and in this country appears to be considerable. It is claimed that there are about 6,000 homœopaths, so called, in the United States, giving a ratio to regular practitioners of about 1 to 10.

A MODEST FRIEND TO HUMANITY AND THE MEDICAL SOCIETY OF NEW YORK.—A letter has strayed into our hands addressed "To the Medical Society of New York." The author writes : "Sirs I adress to inform you after all the artful efforts of our smartest men i have selected 9 ingrediences of the vegetations of the Earth to Cure all Manner of Blood Deseases scrofula it never fails in no form or stage privat Deseases of all kinds olde sores or Cifulis and Catarrh of the head or any Desease Caused by impurity of the Blood it also renovates the Stomac bowels and liver Beyornt anything ever got up and Can be established as the greatest Medicen nowe in the world. . . . Now a reasonable salery will make this great matter known to the Society

"addres Dr. ———,

"Henry Co. Ky."

THE HUNTERIAN ORATION was delivered on February 14th by Mr. Spencer Wells. The orator began with the following interesting account of the origin and purpose of the endowment : "Just seventy years ago, Matthew Baillie and Everard Home, being, to use their own words, 'desirous of showing a lasting mark of respect to the memory of the late Mr. John Hunter, which shall at the same

time express the very high sense they entertain of the very liberal conduct of the Royal College of Surgeons, in supporting and preserving the Hunterian Collection,' agreed with Sir William Blizard and Mr. Cline to endow an 'annual oration, to be called the Hunterian Oration, which shall be read or delivered in the theatre of the said college on the fourteenth day of February in each and every year (being the birthday of John Hunter).' They devised that such oration 'shall be expressive of the merits in comparative anatomy, physiology, and surgery, not only of the said Mr. Hunter, but also of all such persons as are or shall be from time to time deceased, whose labors have contributed to the improvement or extension of chiralurgical science.' After the first oration in 1814, one was delivered every year until 1849. Since that year it has been biennial." Mr. Spencer Wells passed in review the history and work of various deceased members of the Royal College of Surgeons, including Gulliver, Critchett, Soelberg Wells, Clover, and others.

A PLEASANT MINERAL WATER.—The French have a seductive way of putting things. Twenty-six years ago the late Dr. Amédée Latour, writing of a still popular French mineral water, said : "It is the good God who created the waters of Saint-Galmier, but it was an intelligent man, M. Badoit, who discovered them, and two wide-awake physicians who made their fortunes out of them. . . . The water of Saint-Galmier," continues Latour, "is the amiable companion of the student, the useful ally of the enteralgic, the intimate friend of every lady afflicted with 'vapors' or threatened with corpulence, and the inestimable benefactor of the gourmet and dyspeptic."

THE CLIMATE OF SANTA BARBARA AS COMPARED WITH THAT OF THE MEDITERRANEAN COAST.—The following careful and impartial account of the climate of Santa Barbara, written by a correspondent of *The Tribune*, may be of service to our readers, since such contradictory opinions are given regarding this health resort : "The good days at Santa Barbara are among the most delightful in the world ; and there are few days here in winter when the most delicate invalid may not stay out of doors as long as he has the strength to walk or to ride. The ordinary temperature is from five to ten degrees higher than that of Mentone ; the air is soft and genial ; the dampness of the ocean is hardly perceptible in the upper part of the town, and I know of no seaside place, except on the Riviera which is upon the whole so dry. Santa Barbara, moreover, is free from serious drawbacks which impair the value of all the Mediterranean health resorts—such as the bad company, the bad smells, and the violent contrasts of temperature between sun and shade, the open country and the narrow streets.

"On the other hand the California town has its faults. A raw wind, loaded with chilly moisture, does sometimes blow in from the sea. Fogs are not uncommon. Sudden changes of temperature are frequent and vexatious. Rain occurs only between April and December. Occasionally there are cold and blustering days, like those of March in the East."

SYPHILITIC SYNOVITIS.—Dr. Mracek states that this rare affection is observed among the secondary phenomena of the syphilitic infection. It may attack one or several joints, the knee and the ankle being most frequently invaded. If the patient has already suffered from an arthritis, the same joint will be affected by the specific disease. A recent synovitis of this kind is readily amenable to anti-syphilitic treatment, but later its cure is more difficult, and joint-motion is usually compromised. Relapses are frequent. Local treatment consists in immobilization of the joint with massage, when the affection has become chronic. The author also recommends painting with iodine, compression, and in some cases application of ice to the articulation.—*Annales de Dermatologie et de Syphiligraphie*, December 25, 1882.

ON VARIOLA.

ITS DEFINITION, HISTORY, CAUSE, VARIETIES, PROGNOSIS, AND TREATMENT.

By J. N. McCHESNEY, M.D.,

LATE ONE OF THE ATTENDING PHYSICIANS TO THE HOSPITAL FOR CONTAGIOUS DISEASES OF THE CITY OF NEW YORK.

Definition and History.—Variola, or small-pox, is a febrile, eruptive, infectious, and contagious, disease, depending upon a specific, morbid poison, the symptoms of which, after a period of incubation of from twelve to fourteen days, result in an eruption on the surface of the body, which passes through the regular stages of macule, papule, vesicle, pustule, and desiccation, terminating with desquamation.

An exhaustive review of the history of variola would far exceed both the purpose and limit of this article.

Although much time and careful research have been expended in trying to discover the origin of the disease, all efforts have thus far been without definite success. According to the most authentic account, the disease originated, about A.D. 544, in Egypt, whence it spread to Constantinople. In 569 it made its appearance in the Abyssinian army, then besieging Mecca, with such virulence as to compel the abandonment of the siege. During the latter part of the sixth and the whole of the seventh centuries it raged in Egypt and spread into Asia and Africa. It was introduced into Europe by the Saracens upon their invasions of Spain, Sicily, Italy, and France, and gradually extended northward, reaching Saxony, Switzerland, and England in the latter part of the ninth or first of the tenth century. The Spaniards transported the infection to St. Domingo and Cuba about 1520. It was carried to Mexico in 1527, where it raged with great virulence, destroying millions of the inhabitants. Thence the disease rapidly extended over the whole of the Western hemisphere.

Etiology.—Variola spreads by contagion, and cases of supposed spontaneous origin can always, with proper care, be traced to a person who has suffered from a recent attack, or to infected articles.

The morbid principle is contained both in the pustules and in the emanations from the body of a patient suffering from the disease. It is contagious from the beginning of the stage of invasion until the last trace of the desquamative process has passed away.

The infection is contained in the breath, which has been known to convey the disease before the eruption had made its appearance, and it has been communicated both by the virus and the emanations of a dead body. A case¹ has been recorded in which the contagion was communicated from a dead body, though death had taken place before the development of the eruption. "The patient, a medical student, died suddenly in this city, the chief symptoms being gastric with great exhaustion. At the autopsy a few petechiæ were observed on the body. The coffin was taken home to a New England village for burial, and at the funeral some of the relatives opened it to look at the face. Eight of the number present were attacked with small-pox. No

other persons in the neighborhood contracted the disease." In a Western medical college, a year or more ago, a number of students contracted it from a body which was being dissected. A very slight exposure is often sufficient for acquiring the disease. We have met with one or two cases in which there was every reason to believe that the contagion was acquired while riding in the street cars. Many patients are unable to give any history of exposure. The disease is communicable in all of its stages, but the pustular and desquamative stages are most dangerous. Exposure to the same case may give rise in one instance to a mild, and in another to a severe form of the disease; and exposure to the mildest form of small-pox (commonly known as varioloid) may give rise to the worst variety.

No age is exempt from it; we have met with it in a child of three weeks, and in a patient of seventy-nine years. In some instances the disease has been contracted before birth and nearly the whole period of incubation passed in utero, the eruption making its appearance on the child when it was four or five days old. The child may be born with the eruption on its body, or presenting evidences of having passed through an attack in utero. Authentic cases are on record in which the disease has been communicated to the fœtus without the mother passing through a regular attack; these cases may be explained by the fact that the mother had that form of the disease in which there is no eruption—variola sine variolis. As a rule, every individual is more or less susceptible to the contagion of variola. Rare instances are met with in which persons, unprotected by either inoculation or vaccination, though constantly exposed, escape the disease. A physician friend of the writer, who has never been successfully vaccinated, though repeated attempts have been made, has escaped, notwithstanding constant exposure to every variety of the disease under almost every circumstance; and though he has made autopsies on the worst cases which had died in the suppurative stage, and has even received wounds of the finger while thus engaged, no symptoms beyond a little septic trouble have ever been manifested. This can only be ascribed to a peculiar idiosyncrasy as yet unexplained.

Though uterine life does not exclude the danger of infection, the fœtus is less liable than the child under two years of age.

The existence of chronic diseases affords no protection against the contagion of variola, though patients, while in the active stages of the other eruptive fevers, appear to escape infection.

The dark-skinned races are regarded as peculiarly susceptible, and the mortality among the negro and the Indian races is very great. In 1881, in the New York Hospital for contagious diseases, the mortality among the negroes was ten per cent. greater than among whites.

The general opinion is that small-pox prevails to a greater degree in winter than in any other season of the year. Cold weather, by keeping a larger number of people within doors and the avenues to ventilation closed, doubtless does contribute to the spread of the disease, but the records of small-pox hospitals show that a larger number of patients are admitted in May than in any other month of the year. When the disease has begun to prevail it continues throughout the year uninfluenced by winter or summer.

As a rule, one attack renders an individual insusceptible for the remainder of his life. To this rule, however,

¹ Dickson, in American Journal of the Medical Sciences, July, 1862.

there are occasional exceptions. We have met with two cases in which there was a second attack.

Inoculation does not always give perfect immunity; we have seen one case that gave a history and presented the scars of inoculation. The form of small-pox was very mild.

The poison is readily conveyed by clothing and other articles worn and used by a patient, and the contagion may be retained in them for an indefinite period. We recall an instance where the disease was conveyed to a shoemaker who repaired the soles of a pair of shoes which had been worn by an attendant about a room occupied by a patient desquamating from small-pox. Infected clothing which has been buried (a popular method in country districts of disposing of the clothing and bedding of persons who have suffered from variola) has been resurrected and become the starting-point of epidemics. Healthy persons who have been sufficiently exposed may carry the contagion in their clothing and infect others, though they themselves escape.

Varieties.—Six varieties of variola are generally described: 1, Variola discreta, when the pocks stand distinct and separate from each other; 2, variola semi-confluent, when there is partial coalescence of the eruption; 3, variola confluent, when the pustules run into each other; 4, variola hemorrhagica, nigra, or black small-pox, when the vesicles are filled with red blood-corpuscles; 5, variola corymbosa, when the eruption is arranged in bunches or clusters; 6, variola anomala, when it occurs complicated with other diseases, or presenting unusual symptoms.

A mild form of the disease occurring in persons previously vaccinated is commonly described under the term of varioloid. The name is one which should be discarded. Its use has been the source of much confusion and great injury on account of the popular opinion that varioloid is not dangerous. This is probably true in respect to the patient himself, but fatally false in regard to the community in which he is permitted to go at large. We remember hearing a physician of considerable practice in this city say that he met with many cases of varioloid but did not consider them of sufficient importance to report to the health authorities, and that, too, when small-pox was epidemic. That the laity should consider varioloid harmless is not to be wondered at when we hear such expressions from members of the profession. Mild cases of variola, without regard to previous vaccination, should be classed as discrete small-pox. In mild forms, while there is little or no danger to the patient himself, he is more dangerous to the community in which he lives than a patient confined to his bed with the worst form of the disease, since, as frequently happens, no significance is attached to the mild symptoms that occasionally precede the eruption, or the eruption itself may be so scant as to fail to attract his attention, or the notice of those about him. This is often the source of the unexplained appearance of the disease in isolated localities. The epidemic through which this city has just passed was introduced in the person of an engineer who came from a neighboring city where small-pox was prevailing, during the incubative stage of the disease. His attack was so mild that he did not leave his engine-room or quit his work, yet, as a result of this, several cases appeared among his fellow-workmen and among the servants of his boarding-house, two of whom absconded to the lower part of the city, whence the disease began to spread.

Stages.—The course of variola is divided into four stages: 1, Incubation; lasting from the date of the reception of the poison till the initiatory chill, fever, and other symptoms, generally twelve to fourteen days; 2, invasion, or primary fever, lasting from the first general disturbance to the appearance of the eruption, about two to four days; 3, eruptive, or stage of maturation, lasting about nine days; 4, suppurative stage, secondary fever, desiccation, and desquamation, which is of variable duration.

These stages may be shorter or more prolonged under certain circumstances, notably shortened and modified after vaccination.

Incubation.—During the period of incubation there are no manifestations of the approach of the disease; the patient is as well as usual and able to attend to his work. In some exceptional instances there may be a certain feeling of uneasiness or foreboding of the approach of sickness.

Invasion.—The stage of invasion is generally ushered in by a well-pronounced chill, or there may be a series of chills, followed by high temperature, 103–104°, which may, before the eruption appears, reach 106° F. The pulse is full and hard, varying from 110 to 120; respiration is usually increased in frequency; there is great prostration, and the patient staggers if he attempts to walk; the skin may be hot and dry, or bathed in profuse perspiration, which continues throughout the stage. There is great thirst; the lips are parched, the tongue coated with heavy, yellowish white fur, and the breath is fetid; complete anorexia exists; nausea and vomiting are often the most distressing and persistent symptoms. The bowels are in most cases constipated, though diarrhoea is present now and then—most frequently in children. Intense headache is a constant symptom, and continues throughout the stage with more or less severity; the pain is referred to the whole of the head, or may be limited to the frontal region. Intense pain in the lumbar and sacral regions is one of the most striking symptoms. This, in conjunction with nausea and vomiting, is almost invariably present in the initial stage. It is so severe in character that patients almost always complain of it; it appears at the beginning of the stage and continues with unabated severity until the eruption is established. Patients are frequently very restless and are often unable to sleep. Delirium is sometimes present. Convulsions are of frequent occurrence in children. Coma is said to occur, but we have not seen it. Redness and swelling of the pharynx, with pain on deglutition occur in some cases; injection of the conjunctivæ, with lachrymation, is sometimes present; slight cough, with little or no expectoration, is occasionally met with.

Not unfrequently a general erythematous condition of the skin, lasting twenty-four or forty-eight hours, precedes the appearance of the eruption and may be so intense as to lead to mistaking the disease for scarlatina. This, it is generally thought, is followed by a mild eruption, but such has not been our experience. In a number of cases we have seen this condition followed by the hemorrhagic type.

As a rule, if the symptoms of this stage be mild and protracted beyond the usual duration, the eruption will be scant; if, on the contrary, they be of great intensity, a severe type of the disease may be expected. Occasionally the mildest attacks are preceded by prodroma of great intensity, and we have met with cases in which this stage was marked by symptoms of unusual severity, protracted for four days, which have ended without the appearance of the eruption.

The most significant symptoms of the initial stage are the acute pain in the small of the back, the obstinate nausea and vomiting; and when it is known that there has been exposure to contagion, these go far to prove that the person is about to be the subject of an attack of variola.

Stage of eruption.—The eruption of variola makes its appearance on the third day—or after forty-eight hours, and is first noticed about the alæ of the nose, corners of the mouth, and the chin. It appears about the same time on the fronts of the wrists; next on the trunk and arms, and last on the legs and feet. It is first seen as small red spots or macules, which rapidly become elevated and hard, forming papules; these are small, rounded, and have a peculiar hardened feeling, likened to a shot under the skin. On the face the eruption is usually much

more abundant than on the body, frequently being confluent there while it is discrete on the body. If it be confluent there will be a general redness and granular-looking swelling of the face, particularly of the forehead. A tendency to arrangement in groups of threes and fives is sometimes observed, best seen on the arms and back of the trunk.

The eruption makes its appearance sooner and in greater abundance, in the neighborhood of recent wounds, or where there has been any irritation of the skin. One patient that we remember had received a recent abrasion extending from above the elbow to the wrist; the eruption was first noticed extending along both sides of this, and in greater abundance than elsewhere. We have seen several instances in which the application of kerosene oil around the neck for the sore throat had brought out the papules in great abundance; the application of mustard poultices produces the same effect. We recall one case, in a woman recently confined, on whom the eruption made its appearance in great profusion over that portion of the body covered by the binder, several hours before it was seen elsewhere.

About the same time the eruption appears on the skin it may be observed on the soft palate, pharynx, inside of the lips and cheeks, and on the tongue. Here it appears as small, round, opaque spots, which do not form vesicles and pustules. Points of eruption also occur on the conjunctiva. When the eruption is abundant in the mouth it increases the flow of saliva; in the fauces it causes difficulty in swallowing; in the air-passages it occasions cough and hoarseness; on the conjunctiva it increases the secretion of tears, and gives rise to conjunctivitis and to photophobia.

Vesicular stage.—Twenty four hours after the first appearance of the eruption a clear fluid makes its appearance in the papules, which now become vesicles. These enlarge until they attain the size of a small pea. Just before the vesicles become fully distended there is a cup-shaped depression in their centre, which is known as umbilication and constitutes a sign of diagnostic importance. Umbilication does not appear in every vesicle; it is not found in those of the palms of the hands and soles of the feet. This appearance has been attributed to the presence of bands, passing from the centre of the roof to the floor of the vesicle, which hold down the centre while the sides of the vesicle are distended by the accumulation of serum.

When the eruption is well established, there is an amelioration or subsidence of all the distressing symptoms of the initiatory stage. The temperature falls to near the normal, a sign of great diagnostic value; the nausea and vomiting cease; the lumbar pains disappear; the appetite returns; the patient gets up, says he feels well and often expresses a desire to go about his daily avocation. In the severer types of the disease these changes are less marked, and the discomfort may be only slightly, if at all, modified.

From the fifth to the seventh day the vesicles become fully distended; they lose their umbilicated appearance; there is an opaque ring at the circumference, inside this a clear ring with an opaque spot in the centre; their contents gradually change, first becoming opalescent, then turbid, and finally purulent. These changes occupy about two days, and the suppurative stage is thus established at about the eighth or ninth day of the disease, and the sixth of the eruption.

The changes which take place in the eruption occur in the order in which it makes its appearance, so that it may be seen in one stage on the face and arms, and in another and earlier stage on the legs and feet.

The skin surrounding the bases of the pustules is red and swollen, forming what is termed the areola. The tissues of the head and face become greatly swollen; the oedema of the eyelids is often so great as to close the eyes; the features are obliterated, and the patient becomes wholly unrecognizable. The presence of

pustules on the scalp causes considerable swelling, so that pressure upon that part occasions severe pain. The swelling of the pocks in the palms of the hands, especially on the finger-tips and in the soles of the feet gives rise to agonizing pain, not unlike that of paronychia. This pain is due to the resistance which the toughened and thickened skin of those parts offers to distention, and to the pressure upon the terminal nerves.

With the stage of suppuration the fever returns and reaches 103° to 104° , and may continue for four or five days in cases of ordinary severity. This elevation is called the suppurative or secondary fever. The pulse becomes frequent, and there is a return of the general discomfort of the initial stage. Delirium is frequent and, though it may be passive, is sometimes so active as to necessitate restraint. The throat symptoms are intensified; swallowing becomes painful and difficult; the nose becomes stopped; there is a hoarse cough, and the voice is frequently inaudible. Diarrhoea is occasionally present and is always to be considered an unfavorable symptom.

Desiccation.—Desiccation begins usually about the twelfth day. Some of the pustules rupture from over distention; their contents escape and dry into yellow crusts. Others dry up and form brownish scabs. In the palms of the hands and soles of the feet, where the cuticle is thicker, the pustules dry down into hard, brownish spots, which are the last to disappear and frequently retain some of their contents after desquamation is well advanced on all other parts of the body. We have frequently found persons going about with these hard brown spots in their palms and soles, and contagion is undoubtedly spread by them.

The scabs fall off, leaving darkly pigmented cicatrices, the number being in proportion to the amount and severity of the eruption. The whole body may be covered with these stained spots, but the face generally suffers most. This staining gradually fades out and, if the destruction of tissue has not been very great, the scars become less and less noticeable. Where there has been much ulceration, as is common on the face, the pitting is deep and permanent. Six to ten days is the usual duration of the stage of desquamation.

In some cases when the ulceration about the cheeks and alæ of the nose has been deep the scabs show a tendency to adhere longer than in other situations, and by confining the pus increase the ulceration. When they are removed the surface presents a worm-eaten appearance which continues for some time after recovery, but finally disappears almost entirely.

As desiccation and desquamation proceed the fever becomes less and other symptoms disappear; appetite returns, the patient begins to improve and goes on to convalescence.

Complications, particularly erysipelas and furuncles, are most apt to occur during the stage of desiccation. These prolong convalescence, and not unfrequently bring about a fatal termination when all danger from the small-pox is passed.

The symptoms above described are those that occur in natural or unmodified variola, and usually extend over a period of seventeen to twenty-one days.

In modified small-pox, commonly called varioloid, the symptoms and course of the different stages are very irregular, and the duration of the stages, as a rule, is very much shortened. The appearance of the eruption is occasionally delayed to the fourth day. It is not unusual to see the eruption abort in the various stages. A few of the vari are arrested in the papular and vesicular stages, others develop and reach maturation in a shorter time than usual, desiccation takes place early, desquamation is rapid, and the scabs fall off, leaving little or no pitting. The stage of invasion in some cases of modified small-pox is attended with the severest symptoms, yet the eruption that follows is slight and of short duration. In these cases there is little or no suppuration, consequently there is no secondary or suppurative fever.

Variola semiconfluens.—In semiconfluent small-pox there are patches of coalescing pustules on different parts of the body. The symptoms and course are those described in the natural variety, perhaps a little more intense. It is the next simplest form to the discrete variety and is generally not attended with any great danger to life, except in children, or from some complication, as erysipelas, pneumonia, pleurisy, etc.

Variola confluens.—This is the form of the disease in which the pustules coalesce over the whole surface of the body. The symptoms preceding the eruption are greatly intensified, and their severity indicates that the attack is to be of the worst nature. Beginning with a pronounced chill, or there may be several chills, the temperature is high, 104° to 106° ; the pulse is rapid; the headache and lumbar pains are of unusual intensity; the nausea and vomiting are distressing and persistent; the patient is wakeful and intensely restless; there is tremulousness of the hands and lips; delirium is almost always present, and is active, violent, and often maniacal in character. The patient cannot be kept in bed, but is constantly trying to escape from some imaginary pursuer, who he fancies is trying to injure him. Under these delusions we have known patients to jump from windows and receive fatal injuries. Occasionally there is a tendency to do themselves injury, and patients have committed suicide while in this state. Such cases require close, unremitting watchfulness, and often it is necessary to use the straight-jacket or to strap them to their beds to prevent accident.

In this variety the eruption makes its appearance sometimes as early as the second day, and develops far more rapidly than in ordinary cases. The papules are so numerous and close together as to cause a general redness and granular swelling of the forehead, face, and arms; they spread rapidly over the whole body. The swelling about the head and face is very great, closing the eyes and often disfiguring the patient beyond recognition. There is general coalescence of the pustules, so that the eruption is one mass; the cuticle on the forehead, backs of the forearms, wrists and hands is completely raised from the subjacent tissues, forming large bullæ; frequently these burst or are broken, leaving large raw surfaces which exude bloody serum. The eruption is equally abundant on the mucous membrane of the nose, mouth, pharynx, œsophagus and larynx, and extends into the trachea. The tongue becomes inflamed and greatly swollen, so much so in three cases under our care as to fill the mouth and render asphyxia imminent. A viscid, sticky secretion is formed in the mouth and throat, which is expelled with great difficulty, and occasions the patient much annoyance. He complains of sore throat and great difficulty of swallowing; cough is excited by attempts to take food, and fluids often regurgitate through the nose. There is a hoarse cough; the voice is a harsh whisper, or becomes entirely inaudible. The swelling of the air-passages, together with the accumulation of this viscid secretion, frequently renders respiration exceedingly difficult, and at times impossible. The proper aëration of the blood is thus interfered with; the surface becomes livid; the eruption turns a dull purplish hue; there is great prostration; the delirium changes to the low muttering kind, and death usually ensues.

In some cases of confluent small-pox the pustules do not fill out but remain flat, and present a dirty white, pasty appearance. Cases with this flat confluent eruption almost invariably terminate in death.

Confluent variola causes the greatest number of deaths among the unvaccinated—death being due to the extensive suppuration.

Variola corymbosa.—The eruption in this variety of small-pox is arranged in bunches or clusters, and takes its name from the fancied resemblance to a cluster of ivy-berries. It is a rare and usually very fatal form of the disease. There were only two or three cases admitted to the Riverside Hospital during the years 1881 and 1882,

all of whom died. In the London Hospital, in a period of thirty years, there were 104 cases of this variety; 29 were unvaccinated, 13 of whom died, or forty-four per cent.; 74 had been vaccinated, 32 of whom died; 1 had been inoculated and died; 2 died of complications; which gives a mortality of forty-one per cent. in the vaccinated.

Variola hemorrhagica, commonly known as the "black pox," is that variety in which the vesicles become filled with red blood-corpuscles. From the beginning the symptoms are very intense; the patient frequently succumbs from the intensity of blood poisoning before the true nature of the disease is determined, or even suspected. Many cases of this nature occur in inland towns, and, being unrecognized, are the cause of serious epidemics. In the fall of 1881, in a village of an adjoining State, a peculiar fever occurred in the person of a lady resident of that place. The diagnosis of typho-malarial fever was made. The disease proved very malignant, and death occurred in five days from the beginning of her illness. A public funeral was held which was largely attended. In due time a brother of the deceased, who had nursed her, was similarly attacked and the same diagnosis made. This case was seen before its termination by an eminent physician of this city and the diagnosis of hemorrhagic small-pox made. Death occurred at the end of a week. From these a number of cases of small-pox, of different varieties, developed, and the disease assumed epidemic proportions.

Of this form of variola there are two types. In one, the hemorrhages take place into the pocks after the vesicles are developed; in the other, the eruption is petechial from the start.

In petechial hemorrhagic small-pox the stage of invasion is of great intensity, and the eruption not unfrequently makes its appearance on the second day, but is slowly developed. From the soft nature of the spots and their bright red color they are often mistaken for measles. Unlike the eruption in the other varieties of the disease, the macules do not change to papules. There may be a slight elevation above the surrounding surface, but there is an absence of that hard, shotty feeling so characteristic of the papules in other forms. The spots are first seen about the lips and chin. Frequently they appear earlier and are better defined about the axillary folds, on the fronts of the elbows, the sides of the abdomen, and the inner face of the thighs where the skin is whiter and thinner. They vary in size from that of a millet-seed to two or three lines in breadth. At first they are a bright-red, clarety color, then become purplish, and subsequently a deep blue. They are slightly raised above the surface, and pressure does not efface them, even momentarily. This type of hemorrhagic variola usually terminates fatally in less than a week.

In the other type of hemorrhagic small-pox the vesicle is filled with bloody serum. Umbilication is present, but requires closer observation to detect than in the ordinary vesicle. Bullæ of different sizes filled with bloody serum are frequently observed at various places. The blood in the vesicles undergoes further change, becoming darker, almost black; hence the name "black small-pox."

Simultaneously with the appearance and development of the eruption hemorrhages occur from all of the mucous surfaces. Epistaxis, which is frequently difficult to control, is one of the earlier symptoms. The gums bleed; there are hemorrhagic spots on the soft palate; the expectoration is abundant and tinged with blood, or occasionally composed of pure blood. There may be vomiting of blood. The conjunctivæ are intensely congested, and often the effusion of blood beneath the conjunctiva is so great as to raise it above the cornea. Blood is also found in the urine and in the discharges from the bowels. In the female the menstrual flow is brought on, and is very profuse. If pregnancy exist, abortion takes place early, and the child is usually dead. Prostration is marked; the pulse rapid and weak; respiration shallow and imperfectly performed; the temperature is only

moderately high, and, if the hemorrhages have been prolonged, may fall below normal before death.

The mind is often clear to the end; the patient hopeful and unconscious of the nearness of death. In one case we recall telling the patient that if he had any messages for his family, or any requests to make, he had better attend to them at once. He seemed surprised, and said, "You don't think I will die, do you, doctor?" and it was with difficulty that he was convinced of the short time he had to live. This was about 2 P.M. Death occurred at five o'clock.

Delirium, if it occur, is of the low muttering kind; there is twitching of the fingers and picking of the bed-clothing; the lips are cracked; the teeth and gums covered with dark-brown sordes; the tongue dries into a blackened mass with deep fissures, and cannot be protruded; deglutition becomes impossible. Death commonly occurs about the fifth day of the eruption.

This description applies to the confluent variety of hemorrhagic small-pox. The eruption may be discrete, under which circumstance recovery not infrequently takes place. The semi-confluent eruption increases the danger.

Blood is often seen in the pustules on the feet and legs in those patients who leave their beds or keep their feet dependent. This is due to mechanical rather than other causes, and does not constitute any form of hemorrhagic variola. The following are illustrative cases:

CASE I.—*Confluent hemorrhagic small-pox*.—Henry W.—; aged fifty; Germany; orderly at this hospital. July 5th complained of a tired feeling; arms and legs felt heavy. In the evening had a chill lasting a few moments; appetite much impaired, but no nausea.

July 6th.—The symptoms of yesterday more intense; appetite entirely lost; pains in head, small of back, and extremities; sleep fair.

July 7th, A.M.—More chills; pains continue; sense of weight in epigastrium; some fever; no nausea, no epistaxis; constipated. P.M.—A macular eruption in scanty amount on various parts of body; maculae small; gives history of imperfect vaccination.

July 8th, 10 A.M.—Pulse, 108; temperature, 103°; respiration, 38. Eruption becoming papular. 5 P.M.—Pulse, 112; temperature, 104.2°; respiration, 38. 6 P.M.—Pulse, 100; temperature, 104°; respiration, 28.

July 9th, 8.30 A.M.—Pulse, 92; temperature, 101.3°; respiration, 22. 5 P.M.—Pulse, 104; temperature, 104.2°; respiration, 26. Appetite better, sleep better; headache not constant, and not nearly so intense; general feeling much more comfortable. The eruption increased somewhat in amount. A very few vesicles may be seen.

July 10th, 9.30 A.M.—Pulse, 90; temperature, 102.3°; respiration, 26. Eruption slowly increasing; number of vesicles greater, but they are still few, with here and there one which is umbilicated. Constipation relieved with salines. 5 P.M.—Pulse, 88; temperature, 102°; respiration, 26.

July 11th, 11 A.M.—Temperature, 99°.

July 12th, 9 A.M.—Pulse, 80; temperature, 100°; respiration, 20. A marked increase in the amount of the eruption during the last thirty-six hours, so that now it is very abundant. The color of the areolæ of the spots much deeper. The eruption more generally vesicular; on the face it is pustular, and there and on portions of the body elsewhere it is becoming confluent. The cheeks and lower lids, the nose and the upper lip are swollen considerably; complains of a throbbing, band-like feeling across the nose; skin sensitive generally; a number of vesicles on mucous membrane of mouth; no difficulty in deglutition or respiration, except a feeling of slight constriction around the chest; a slight coryza. No vesicles noticed on conjunctivæ, but there is some congestion and photophobia. Appetite good; sleep broken. 5 P.M.—Pulse, 92; temperature, 100.3°; respiration, 24.

July 13th, 9 A.M.—Pulse, 110; temperature, 100.3°; respiration, 20. 5 P.M.—Pulse, 108; temperature, 101°; respiration, 21.

July 14th, 9 A.M.—Pulse, 115; temperature, 100.3°; respiration, 22. 5 P.M.—Pulse, 127; temperature, 102°; respiration, 29.

July 15th, 9 A.M.—Pulse, 120; temperature, 101.2°; respiration, 24. 5.30 P.M.—Pulse, 128; temperature, 103°; respiration, 24. Suppuration progressing over the whole surface; hemorrhages have occurred into a number of pustules, especially on hands and forearms and legs; no large hemorrhagic spots. Appetite continues fair; sleep poor. Is a little delirious at night.

July 16th, 9 A.M.—Pulse, 118; temperature, 102.1°; respiration, 24. 5 P.M.—Pulse, 124; temperature, 104.3°; respiration, 28.

July 17th, 8.30 A.M.—Pulse, 112; temperature, 101.5°; respiration, 24. 7.15 P.M.—Pulse, 120; temperature, 104.2°; respiration, 28.

July 18th, 8.30 A.M.—Pulse, 112; temperature, 103.1°; respiration, 24. 6.15 P.M.—Pulse, 112; temperature, 102.3°; respiration, 24.

July 19th, 9 A.M.—Pulse, 107; temperature, 100.3°; respiration, 24. Has diarrhoea. Desiccating. 5 P.M.—Pulse, 112; temperature, 102.5°; respiration, 29.

July 20th, 9.30 A.M.—Pulse, 104; temperature, 101.3°; respiration, 24. 7 P.M.—Pulse, 112; temperature, 102.3°; respiration, 28. Diarrhoea checked; oedematous swelling of feet and legs; large bullæ of sanguinolent fluid on feet and legs, and smaller ones on arms. Urine of normal quantity and free from albumen. Larvæ up to a third of an inch in length in ears and under scabs on face.

July 21st, 9.30 A.M.—Pulse, 104; temperature, 101.1°; respiration, 25. 5.15 P.M.—Pulse, 108; temperature, 101.3°; respiration, 28.

July 22d, 11 A.M.—Pulse, 108; temperature, 99.1°; respiration, 24. 5.30 P.M.—Pulse, 118; temperature, 103°; respiration, 27. Desiccation far advanced everywhere, except on face, where suppuration is still active.

July 23d, 9.30 A.M.—Pulse, 104; temperature, 98.5°; respiration, 24. 5.30 P.M.—Pulse, 114; temperature, 102°; respiration, 28.

July 24th, 9 A.M.—Pulse, 104; temperature, 100°; respiration, 24. 5 P.M.—Pulse, 100; temperature, 100.3°; respiration, 24. Suppuration ceased on face.

July 25th, 10 A.M.—Pulse, 104; temperature, 99.1°; respiration, 22. 5.30 P.M.—Pulse, 112; temperature, 101.5°; respiration, 24. The oedema of lower extremities somewhat diminished. Is improving rapidly.

July 26th, 9 A.M.—Pulse, 100; temperature, 99.2°; respiration, 24. 5 P.M.—Pulse, 100; temperature, 100.5°; respiration, 24.

July 27th, 10 A.M.—Pulse, 106; temperature, 101.5°; respiration, 26. 5.30 P.M.—Pulse, 100; temperature, 101.4°; respiration, 26.

July 28th, 8.30 P.M.—Pulse, 92; temperature, 99; respiration, 20.

July 29th, 9.30 P.M.—Pulse, 100; temperature, 98.5°; respiration, 20.

August.—An abscess in the site of an old wound in the back between the shoulders, opened and several drachms of pus evacuated.

August 20th.—Desiccation progressing very slowly in face, elsewhere desquamation is about completed.

October 6th.—Desquamation now completed. The pitting is very extensive on the face; on other parts there is none at all. Discharged cured.

CASE II.—*Confluent hemorrhagic small-pox*.—John P. R.—; aged twenty-seven; United States; butcher; arrived at New York, July 23d, per S. S. De Ruyster from Antwerp. Admitted 7.30 A.M., July 24th. No history of sickness previous to admission obtained from patient.

July 24th, 8 A.M.—Pulse, 96; temperature, 99.2°; respiration, 17. Everywhere on the surface of the patient's body, is a very abundant vesicular eruption, which for the most part is discrete, though upon the face, backs of hands, and in spots elsewhere it is confluent. That on

the face and dorsal surface of the hands has the appearance of a superficial blister, and is but slightly raised. Where the eruption is discrete the vesicles are small and the inflammation around their bases shows only a pale pink color. Many of the vesicles are umbilicated. The tongue and buccal mucous membrane also show a similar discrete eruption. Pulse is quick, thready, and strikes with considerable force. Patient is stupid and not able to give an intelligent account of his illness. 5 P.M.—Pulse, 100; temperature, 100.3°; respiration, 22.

July 25th, 8 A.M.—Pulse, 104; temperature, 101°; respiration, 22. In a stupor day and night, and at times attempts to leave the bed. Offers no objection to the administration of his food. Pulse weaker and still thready. 5 P.M.—Pulse, 124; temperature, 104.2°; respiration, 30.

July 26th, 8 A.M.—Pulse, 120; temperature, 103°; respiration, 25. 5 P.M.—Pulse, 136; temperature, 106.2°; respiration, 35. The eruption, especially on the legs and forearms, now has a purplish look. On the fingers are a few hemorrhagic spots of small areas. Sponged with cold water. 7.30 P.M.—Temperature, 106.2°. Placed patient on Kibbee cot, and two pailfuls of cold water used. After the bath the record of the pulse, temperature, and respiration was. 8 P.M.—Pulse, 96; temperature, 98.2°; respiration, 20. Mind clear. Pulse strong, and no longer thready. Skin warm, but patient feels chilly. Has been constipated since admission, relieved by enema. 10 P.M.—Pulse, 107; temperature, 100°.

July 27th, 8 A.M.—Pulse, 108; temperature, 102½°; respiration, 20. 3 P.M.—Pulse, 128; temperature, 105°; respiration, 36. Pulse feeble and thready. Kibbee cot. After bath: pulse, 100; temperature, 99°. 5 P.M.—Pulse, 104; temperature, 101.1°; respiration, 27. 7 P.M.—Pulse, 120; temperature, 103.3°; respiration, 30. Kibbee cot; after bath, pulse, 100; temperature, 99.3°.

July 28th, 8 A.M.—Pulse, 108; temperature, 101.1°; respiration, 23. 5 P.M.—Pulse, 108; temperature, 101.2°; respiration, 31.

July 29th, 8 A.M.—Pulse, 108; temperature, 99.3°; respiration, 29. 2.30 P.M.—Pulse, 120; temperature, 101°; respiration, 39. 5 P.M.—Pulse, 120; temperature, 101.3°; respiration, 43. Died about 7 P.M., July 29th.

(To be continued.)

GREAT MEN AND SMALL HEADS.—"It is usually supposed," says the *Athenæum*, "that men of great intellectual powers have large and massive heads. But this theory, which Dr. Gilbert, physician to Queen Elizabeth, was the first to suggest, is not borne out by facts. An examination of busts, pictures, medallions, intaglios, etc., of the world's famous celebrities almost tends the other way. In the earlier paintings, it is true, men are distinguished by their large heads, but this is attributable to the painters, who agreed with the general opinion, and wished to flatter their sitters. A receding forehead is mostly condemned. Nevertheless, this feature is found in Alexander the Great, and, to a lesser degree in Julius Cæsar. The head of Frederick the Great receded dreadfully. Other great men have had positively small heads. Lord Byron's was 'remarkably small,' as were those of Lord Bacon and Cosmo di Medici. Men of genius of ancient times have only what may be called an ordinary or every-day forehead, and Herodotus, Alcibiades, Plato, Aristotle, and Epicurus, among many others, are mentioned as instances. Some are even low-browed, as Burton, the author of 'The Anatomy of Melancholy,' Sir Thomas Browne, and Dürer. The average forehead of the Greek sculptures in the frieze from the Parthenon is, we are told, 'lower, if anything, than what is seen in modern foreheads.' The gods themselves are represented with 'ordinary, if not low, brows.' Thus it appears that the popular notion on the matter is erroneous, and that there may be great men without big heads."

GLIO-SARCOMA OF THE CEREBELLUM OCCURRING IN A CHILD FOUR AND ONE-HALF YEARS OF AGE.

By L. EMMETT HOLT, A.M., M.D.,

NEW YORK.

LIZZIE B.—came under observation at the Northwestern Dispensary, December 11, 1882. She was carried in by her mother; she having been unable to walk alone for one month. It was stated that the child had not been well since the summer, the first thing noticed being a listlessness and an indisposition to any exertion. Later, fever came on, at first regularly every other day, but without any noticeable chill or sweating. She vomited frequently. Severe neuralgic pains in the forehead, the epigastrium, and the extremities were often complained of. There was complete anorexia, and after a little the bowels became obstinately constipated. Occasional rigidity of the muscles of the back of the neck had been seen, which had been accompanied by pain in this region. The gait was first noticed to be peculiar about three months before she came to the dispensary. She had difficulty in going up and down stairs at first, and was seen to stagger as she walked. This gradually became more pronounced and the mother said "she walked like one drunk." Thus she became at last almost helpless. There had been a general and steady decline in strength and flesh. Of late, the pains at the epigastrium and the extremities had somewhat abated and she complained only of severe occipital pains and of a soreness about the neck or throat. There had been lately no tendency to periodicity in the symptoms. She had had measles and scarlatina about two years before, and though diphtheria was carefully sought no history of this could be obtained.

On examination the patient was found very pale and anæmic, with a heavily furred tongue and a fetid breath. She was unable to stand without considerable assistance. When supported on either side, she walked with great difficulty, constantly crying for fear of falling. The body was balanced awkwardly, rocking to and fro. As she sat upon the mother's lap she was found to be able to execute all the usual movements with the lower and the upper extremities well, though it seemed with a little diminished power, exactly how much it was difficult to say from the age of the patient. The muscles were all rather flabby to the feel, but no comparative atrophy was present. Reflex sensibility of the soles was normal. There was no exaggeration of the patellar reflexes. Handling of the muscles produced so much pain she cried out. No facial or ocular paralysis. The pupils were normal and responded to light well. The tongue was protruded without difficulty. The mind was unaffected. Nothing abnormal was found on examination of the throat, heart, or lungs. The spleen was much enlarged, its vertical dulness measuring four and one-half inches in the posterior axillary line. The head was drawn backward, and the muscles of the neck showed a little rigidity, this could, however, be readily overcome.

There seemed to be no doubt regarding the existence of chronic malarial poisoning; but whether all the symptoms could be referred to that source was the question. This view was taken as a working hypothesis from the following grounds: 1, the history of a fever which at the outset came on periodically; 2, the marked splenic enlargement; 3, the great muscular soreness; 4, the incomplete character of the paralysis.

Quinine sulph. was ordered, gr. xx. per diem.

On December 16th, my friends Drs. V. P. Gibney and L. Putzel saw the case with me, and a more thorough examination was made than hitherto, demonstrating the fact to the satisfaction of all, of the existence of a very marked degree of ataxia in both upper and lower extremities. In putting out the hand to grasp anything, a slow oscillatory movement from side to side took place before the object was seized. A similar thing was noticed when she raised the foot to touch anything. In

walking, when supported a little, she lifted the feet well from the floor, but put them down in an uncertain way. When she stood, the body swayed from side to side without any especial tendency to fall in any direction. She could button and unbutton the clothes, though with some difficulty. There was nothing spasmodic about the movements, and closing the eyes did not appear to make any difference in them. Her general condition had improved very perceptibly under the quinine, and she seemed to have a little more power in the limbs. In fact, grave doubts were expressed as to whether there was any actual paralysis present, the ataxia being considered a sufficient explanation of the inability to walk alone. The different muscular groups were examined electrically, and good responses obtained to a mild faradic current. The disease was still regarded as a malarial neurosis, and it was decided to continue quinine, especially as the child was improving under its use.

The improvement continued for about a week, and then, despite the use of the drug, she grew steadily worse. The bowels, which had yielded to mild laxatives before, again became obstinately constipated; she vomited four or five times a day; she took no food to speak of; once, for twenty-four hours, retention of urine took place. She complained much of severe occipital pains, and sometimes for days together the head would be drawn back into the pillow. Pain about the front of the neck or throat—it could not be determined which—troubled her much, and nothing to explain it could be found. She became very irritable in disposition, though not drowsy. She could move the hands and feet freely, but when laid upon the sofa was unable to change her position.

The temperature had never been above $100\frac{1}{2}^{\circ}$ (rectal), and reached that point only once. The diagnosis of malaria was now given up, and it was thought to be most likely basilar meningitis. The quinine was now discontinued, and the treatment was mainly symptomatic. There was no irregularity of pulse or respiration noticed at any time. A few days before my last examination, which was on January 3, 1883, she was said to have had at times difficulty in "getting out what she wanted to say"—as the mother expressed it. When I saw her she seemed bright, responded intelligently to questions, though the speech seemed to be a little thick. The tongue was protruded normally. No paralysis of face or eye muscles. The pupils were normal and responded to light. The head was drawn in marked opisthotonos, though the muscles of the neck were not rigid. Deglutition had seemed a little interfered with lately. The special senses were not critically tested, though they seemed normal. The ataxia was still present. The diagnosis of tumor was now made quite positively. The child seemed in no immediate danger, but about noon the following day she called for water, drank with avidity, became cyanotic and died quite suddenly, never having had any convulsive movements at any time. The whole duration of the disease, reckoning from the first disturbances in locomotion noticed, was a little less than four months.

Autopsy, made twenty hours after death. Rigor mortis well marked. Nothing abnormal was found in the thoracic organs. Spleen was normal in size but rather firmer than natural. Liver was slightly congested. Right kidney about twice the size of the left, though neither gave any gross evidences of disease.

On removing the calvarium, the dura was seen to be tense and bulging. No evidence of pachymeningitis. As the brain was being removed quite a quantity of clear serum escaped, estimated to be about three ounces. This seemed to come from the ventricles, through the aqueduct of Sylvius principally. The meninges were much congested, but showed no evidence of inflammation or extravasations. On the inferior surface of the cerebellum was a new growth about the size of a hen's egg. It measured two and a half inches antero-posteriorly and one and a half transversely. It occupied nearly the me-

dian line of the cerebellum, projecting posteriorly a little beyond that structure.¹

The specimen was examined by Prof. Wm. H. Welch, who kindly furnished me with the following report: "The tumor occupies the situation of the inferior vermiform process of the cerebellum. It is soft in consistency and bears a considerable resemblance to the normal brain substance, but is redder in color. The shape of the new

Fig. 1.—Inferior surface of the cerebellum; A is the tumor mass.

growth is much like that of the inferior vermiform process, but it is about two or three times larger in size. It has encroached somewhat upon the lateral lobes of the cerebellum, which in the rest of their extent appear normal, as does likewise the superior vermiform process. The ventricles of the brain, particularly the fourth ventricle, are considerably dilated, manifestly by the encroachment of the tumor upon the fourth ventricle.

Fig. 2.—Superior surface of the cerebellum; A is the projecting tumor.

"Microscopically, the tumor is a glio-sarcoma. It is composed of a mass of cells, predominantly round cells, in a finely granular and finely fibrillated matrix. The growth is rich in blood-vessels."

Remarks.—The study of cerebellar disease has, within the past few years, received a valuable contribution from Nothnagel.² The view which he takes seems to me to be able to reconcile many of the hitherto contradictory facts relating to this subject. As my own case corroborates them fully, I will briefly state his conclusions:

First.—Lesions confined to the lateral lobes of the cerebellum are not at present diagnosticable.

Second.—Destructive lesions involving the central lobe, or the vermiform process, are accompanied by muscular

¹ The drawings of the tumor were made by my friend Dr. Frank W. Olds.

² Topische Diagnostik der Gehirnkrankheiten—Art. Cerebellum.

inco-ordination; but this is the only symptom which is diagnostic.

Third.—The inco-ordination from a lesion of the vermiform process is sufficiently characteristic to be distinguished in most, if not all cases, from that of posterior spinal sclerosis. Its peculiarities are a swaying movement of the body in walking, the legs widely separated, the feet raised but slightly, a staggering, a rocking to and fro, and finally falling in any direction. Closing the eyes may or may not increase the difficulty. The spasmodic character of the movements is usually wanting. The group of symptoms so closely simulates those of alcoholic intoxication, that one of Nothnagel's patients was several times locked up by the police for drunkenness.

Fourth.—Vertigo is often an early symptom, and may be the first noticed, but is of no diagnostic importance unless associated with inco-ordination.

Fifth.—The optic is more frequently involved than the other nerves of special sense.

Sixth.—Vomiting is wanting in the stationary and degenerative lesions, but is a common symptom in abscess, hemorrhage, and tumor.

Seventh.—In many cases, especially of tumor, we have occipital neuralgia as a prominent symptom.

The following are occasionally seen, but are accidental, and are to be considered as rather against, than in favor of cerebellar disease: Paraplegia or hemiplegia; paralysis of one-half of the tongue, though disturbances of speech are more frequent; dysphagia, epileptiform attacks, and disturbances of the other special senses.

One point of practical value which this case teaches, is that we should not be too ready to attribute obscure nervous symptoms to malarial poisoning, even in patients in whom indubitable evidences of such poisoning exists; and that a failure of full doses of quinine to affect the symptoms should lead to a careful examination for organic disease of the nerve-centres.

200 WEST FIFTY-SECOND STREET.

LUNATICS AT LARGE 'S. SANE PERSONS IN LUNATIC ASYLUMS.

By N. ROE BRADNER, A.M., M.D.,

LATE OF THE PENNSYLVANIA HOSPITAL FOR THE INSANE, PHILADELPHIA.

In a weekly journal I read, recently, an article entitled "Lunatics at Large," which, although intended as public gossip or general information, contains so much that is of real importance and especially interesting to the profession that I feel prompted to take up the cue, and beg for a few moments the indulgence of the readers of THE MEDICAL RECORD.

It begins as follows: "The number of embryo lunatics at large in this city (New York) is appalling, and continual outbreaks of insanity that we are treated to, such as the mad Frenchman who recently stabbed a dozen helpless women on Fourteenth Street has not resulted in any attempt by the authorities to suppress the lunatics at large." Proceeding it declares with lamentable truth that "people seem to think that an insane person is not dangerous until he or she commits some deed of actual violence;" and if the writer can disabuse his readers of this erroneous and dangerous belief, he will feel that he has accomplished quite as much good as can be expected to result from any one magazine article.

The writer in the journal referred to relates how a lady, who had taken an aversion to pie, screamed with violent excitement when her eye fell upon the offending dish which her son had ordered for the family table, and seizing a carving-knife she chased the young man with great energy and desperation. "But the family say she is not crazy, only eccentric." And of her mother it is related that she is an old lady of three score and ten, and eccentric too, having been discovered one winter's night, on a public street, a considerable distance from home, "shiv-

ering in her night-dress." Again we read: "Only a day or two ago a man came into my office who, if not a raging lunatic, was so near being one that I did not enjoy his visit at all. His hair was half a foot longer than Oscar Wilde's, and hung in beautiful chestnut ringlets down his back; his beard and moustache were long and gray mixed, and he wore a pair of large round spectacles with heavy rims. On his head he wore a black sombrero, and under his arm carried a portfolio." He was further described as a man whose looks would decide a jury of physicians against his sanity, and as follows: "I see this man constantly on the street and expect nothing else than to find some of these days he will become violent and treat us to a massacre in true lunatic style."

Let us now for a moment look at the converse, and each one for himself recount the number of graphic reports of sane persons having been incarcerated in lunatic asylums we have read in the daily papers within the last month. Indeed, the public press almost without exception seems to seize with the fondest avidity, and magnifying to the greatest exaggeration, every case of alleged illegal or improper hospital commitment that is made public by means of the writ of *habeas corpus*. It is, therefore, not surprising that the numerous discharges that have been recently so effected from insane asylums, especially in New York, have produced much sensation among those who believe all they see in the papers; indeed the profound thinker may well be startled when one day he reads that the community is thronged by dangerous lunatics at large, only awaiting a hazard impulse and axe to brain whoever happens to run counter to him, and is the next day informed through the same medium that another, and numerous other sane persons have been discovered incarcerated in lunatic asylums, where are depicted dungeons and horrors that nearly make his hair stand on end; attended by a little hint or history of how they had been kidnapped from homes they alone could make happy. Otherwise how their personal fortune had prompted and conspiracy effected their capture and imprisonment—the conspirators being heartless relatives, unprincipled physicians, and a straw judiciary. It is not my intention to assert on the one hand that sane men may not be unjustly declared insane, and thus deprived of their liberty; nor yet deny that insane and dangerously insane persons do mingle in society that does not yet even dream of the imminent tragedy that may so quickly throw it in consternation. It is true that a great smoke indicates some fire, but I have been intimately acquainted with all the circumstances of some of the lunacy cases that have become sensational and am well aware that they have been made so chiefly by reason of the color given by the reporter who wished to interest his readers. But while the public has been startled, the friends of the patient alarmed, and the hospital authorities annoyed by these sensational newspaper articles, it is not therein that exists the greater evil to which, in this article, I can but briefly, but will pointedly and plainly call your attention. The arrogant presumption of ignorance, if not intemperance, whom chance or political cunning may have elevated to the woolsock—when he ignores philosophy and experience—commanding the doors of asylums to be opened, and those sent abroad who are declared insane by those who are most experienced in insanity, and whose unrestrained liberty may be dangerous to human life, is truly appalling. We have no respect for him who would look down from that exalted position to insult Dr. Kirkbride—if not indeed the whole medical profession—with the strong hint that if he were only clothed with a little greater authority the tables would be turned and the whole crowd of us consigned to the lunatic asylum.

Some months ago a female patient in the Pennsylvania Hospital for the Insane applied to the Court of Common Pleas, through writ of *habeas corpus*, for her discharge. She had been regularly committed by forms and process as provided by existing law of the State of Pennsylvania,

including the sworn statement of Drs. D. F. Woods and Thomas G. Morton that the girl was insane and a proper subject for the hospital. Dr. Kirkbride, the Physician-in-Chief, and who has been so since the foundation of this branch of the hospital, over forty years ago, testified that she had in some measure recovered, and suggested that she might, with propriety, leave the hospital, if she could go where she could be pleasantly and properly surrounded, which he knew would not be the case if she was returned to her father's house, where existed domestic infelicity that he knew would be detrimental to her peace of mind. At this point the August looked down and sneeringly asked the doctor, who had given his exclusive attention to the subject of insanity since before that judge was born, if that was why she was sent to the asylum.

The doctor mildly replied that she was sent to the asylum because she was insane. But what are we to expect toward reform, whether of sane persons in asylums, or lunatics at large, at a tribunal where one of the best, if not, indeed, the best American authority concerning a certain disease, is thus publicly insulted at the bar of justice, and by him of the robes. Because, forsooth, in the goodness of his heart he suggests that a convalescent patient should not be yet exposed to the noxious atmosphere that caused her disease. In another case, where one of our most excellent judges sat to hear the evidence of insanity of a patient who demanded his discharge from the restraint his physicians advised, his Honor consented to take that responsibility—a step, I will venture to say, he has ever regretted, for the patient being deprived of the protection the restraint of the hospital afforded him, immediately destroyed himself. I would convey the idea, then, that to discriminate between sanity and insanity, or those who should or should not be therefore deprived of their liberty, requires not only a *sober* desire to be just, but peculiar skill that can only be acquired by experience.

I may be permitted to illustrate more forcibly by two cases within the scope of my own practice: Colonel S—, aged fifty, a Philadelphia gentleman, who had, until within a few months, enjoyed good health, and was known as the life of his large circle of friends, became, by degrees, dyspeptic, melancholy, and suicidal. His friends placed him in close confinement, and when he, by my order, was closely watched by day and night, that he might not destroy himself, he refused all food until he was in a starving condition.

He seemed to have formed some attachment to me, and I discovered that he valued the principle of truth more highly than happiness or life. Acting upon this information, I made the following bold agreement with him, to which he became a party after much hesitation and pressure: 1, He was to go with me directly and partake of dinner; 2, he was, thereafter, to eat his meals regularly; 3, his meals were to be served in his room; 4, his attendants were to cease to watch him, and he was to be at full liberty, except that he was not to go beyond certain specified limits; 5, this contract was to continue for three weeks and then terminate.

He was a splendid specimen of mankind; of handsome face and form, six feet two inches in height, and in health weighed full two hundred pounds, but at the time of this agreement his weight had been reduced by at least fifty pounds, and by his long fasting he was too weak to walk, except by the help of a cane which he borrowed of me. This singular contract was kept *in toto*, religiously and faithfully. It is now, indeed, to me interesting in the extreme to remember that first meal he ate at my table. He soon after became cheerful—happy, indeed; he was abroad each morning by five o'clock, and was at all times at his liberty.

During the three weeks so spent he regained his strength and a considerable part of the flesh he had lost during his fast, and the pleasure of his daily visits to me is never to be forgotten.

The day previous to that terminating our contract, he came and reminded me of the fact, but circumstances over which neither he nor I had control prevented its renewal. Returning to me on the following day to return my cane and bid me good-bye, he presented the picture of health, and there can be no doubt that any judge deciding such a question on the result of his own personal examination, without the opinion of a physician, and one indeed well experienced in mental diseases, would have pronounced it a shocking outrage to restrain such a man of his liberty. He left our care and we saw him no more forever! His poor lifeless body was afterward found suspended by the neck.

The second case to which I referred is related as follows: A few years ago I was sitting in the private office of a chemist of this city, and although I could not see what was transpiring in the front office, I could distinctly hear. Presently some person entered and began conversation with the clerk, and inadvertently, almost unconsciously, I became interested. The voice forsooth was that of one of my friends and near neighbors, whose sanity had never been questioned, while its statements and arguments were those of a madman. Within one minute, and without seeing this man, I discovered him to be insane, with delusions of the most dangerous character. He had brought several articles of food and a fly, that he said he had taken from his tea, all of which he wished the chemist to analyze, confidently expressing his conviction that his friends were all down on him and wished to destroy his life by means of poison. I knew the physician of the family and immediately informed him of my apprehension. Within a day or two I was consulted as to treatment, and becoming familiar with the circumstances and history, advised his immediate restraint, and he was accordingly placed in a hospital for the insane, where his disease never abated but progressed so rapidly that he died a maniac within a month.

This case, I think, furnishes a forcible illustration of the importance and necessity of experience in determining as to the sanity or insanity of any individual. This gentleman was in the early stage of a form of mental disease most dangerous to the lives of those around him, while the external manifestations were not such as to be recognized, except by those who had previously become acquainted with its symptoms and course.

Between him and the long-haired eccentric described in the early part of this paper, at least ten to one, excepting medical experts, would judge the former to be the more dangerous, while, as I have already said, I consider the latter gentleman was one of the most dangerous of all men to be at large. And now my task would be more than half undone if I did not impress upon the reader and make clear the truth and reason of this which is so simply done.

Self-preservation is the first law of man, and any one is justifiable in causing the death of another, if this be the only means of preventing his own murder. When reason then is dethroned, displaced by delusion, the lunatic believing another, or a score of others, even his nearest friends, are endeavoring and conspiring to kill him, his impulse is to anticipate their attack and slay those, always the most innocent persons, whom his obscure disease leads him to suspect.

2038 RACE STREET.

HYPERIDROSIS OF THE HANDS AND FEET.—Naphthol has been recommended (*Druggist*) as an effective remedy against excessive sweating of the palms, foot-soles, and axillar. These places should be moistened once or twice daily with a mixture of naphthol 5 parts, glycerine 10 parts, and alcohol 100 parts, and afterward dusted, either with pure starch or with a mixture of naphthol 2 parts, starch 100 parts. In case of sweating feet, small pellets of antiseptic cotton should be dipped in the powder and placed between the toes.

THE TREATMENT OF OVARITIS.

By HORATIO R. BIGELOW, M.D.,

WASHINGTON, D. C.

I KNOW of no pathological condition involving the female sexual apparatus which is so unsatisfactory in its treatment, so discouraging to the physician, and so hopeless to the patient, as is oöphoritis. Were absolute rest of ovaries and Fallopian tubes possible, and were it equally possible to reach interstitial and peri-oöphoritis by deep massage, we might expect much from expectant treatment. But participating directly or indirectly, as they do, in every functional change, being subjectively and objectively factors in all mental operations, the ovaries cease to be active only with the cessation of life itself. Equally energetic are the tubes, suffering from transmitted influence, from intrinsic disease, or engaged in the retrogressive metamorphosis and healing process of menstruation. There is no period of physiological rest. The tubes, until the menopause, are either preparing for the catamenia, or are engaged in recovering from the shock. Whether menstruation be a mere expression of ovulation, or whether it depend upon "the exfoliation of the outermost layers of the proliferated mucous membrane of the uterus," or whether it be an especial prerogative of the Fallopian tubes, the direct effect and the transmitted influence are felt along the entire uterine track. The congested ovary, the hemorrhagic tube, in active operation itself and participating by contiguity of structure with the ovary, and the utricular glands of the uterus, are all sympathizing in a physiological event, which may easily be rendered pathological by a want of integrity in the faithful functioning of any part engaged. A past history of constant suffering, of neuralgic aches, painful defecation, a tearing sensation in the ovary, dysmenorrhœa, pains in the back and loins and down the thigh, despondency, dyspepsia and melancholia, a present history of a life miserable and bedridden, and a future which does not bear contemplation, these are common incidents written in the pages of the life history of those who address themselves to the gynecologist for the relief of an oöphoritis. Any chance that offers the slightest hope of respite is eagerly seized. Abdominal section and the removal of the uterine appendages is stripped of terror, and the patient joyously submits to anything that will bring future sunshine. Uteri retroverted or in any way misplaced are supported by pessaries, lacerations are sewed up, vegetations of the endometrium are removed with the curette, cervices are depleted, tonics are administered, but the patient finds no surcease from her suffering. The recurrent peritonitis, or the pains simulating a peritonitis, due to a salpingitis with pus formation in the tube, or to an inflammation or degeneration of the ovary, come around with discouraging regularity and persistency. With as constantly recurring a disregard of the ovary, the seat of the disorder is again relegated to the uterus, the endometrium is again and again medicated, another pessary is applied, the recurrent abdominal inflammation is variously attributed to an old pelvic inflammation, to sympathy, or to a pathological condition within the uterus, and thus and so the woman fades away, carrying along with her the reputation of the physician and the silent evidences of his lack of discrimination.

I do not believe that the cause of this long and varying train of symptoms is ever to be found within the uterus, however misplaced it may be, or in however great a degree its mucous membrane has degenerated. Displaced uteri, lacerations of the cervix, endometritis, endocervicitis, and metritis, have a symptomatology in which, while many symptoms are common to each, other and characteristic ones are sure guides in the location of the difficulty. Neither do I believe that any good results can possibly obtain if the secondary conditions are allowed to obscure the primary. The intercurrent dysmenorrhœa accompanying an oöphoritis, being a mere expression of

deranged ovarian function, will not yield to uterine medication, neither will the dysmenorrhœa, associated with a dislocated uterus, yield to the replacement of that organ, provided there be inflammation or degeneration of the ovary. Misplaced uteri are never accompanied by the same alarming series of symptoms. The inconveniences thus occasioned, in uncomplicated cases, yield readily to pessaries, or to medicated tampons. But it so happens, that oöphoritis is most frequently found in connection with some derangement of the uterus, sufficiently well marked to lead up to the belief that this, of itself, is the *fons et origo* of the patient's illness.

The groin pain, the melancholia and dyspepsia are attributable to the retroverted uterus, and will yield, so it is hoped, to the properly adjusted pessary. The great mischief of the pessary is found in the ease with which it is applied, and in the marvellous and oftentimes imaginative good which it is alleged will follow upon its introduction. Pessaries are only *exceptionally* beneficial. The majority of cases do better without them, and get well faster and with a greater assurance of permanency with medicated tampons. The indiscriminate use of the pessary, and its not infrequent mal-adjustment, are the exciting causes of serious disease. He is a wise man in his generation who, recognizing an oöphoritis, will allow the uterus, no matter however greatly misplaced it may be, to remain just as he happens to find it, and will address himself to the ovary alone; who will assure his patient by a cheerful manner, and will explain to her what he hopes to achieve in the administration of certain remedies. He will much more surely attain his end and the confidence of the woman, by declining to interfere needlessly, by vaginal examination, or by constant attempts to replace the uterus, which only shock her nervous system, and exaggerate the mental disturbance always present. Relieve your patient first of her intolerable suffering and despondency, thus winning her sincere regard, and there will be time enough left to rectify the other matters.

But how shall we relieve the suffering? I protest that I have carried this matter about with me, as a burden, of which I have been unable to disembarass myself by night or day. A case in my own family, so hydra-headed in its ever-changing symptoms, so irresponsible to treatment, so painful to witness, has invested me with a deep sense of a physician's responsibility in such instances, and with a very painful conviction of my own ignorance. The intense desire to relieve, with complete inability to do so, is a species of punishment about as painful as any that one can undergo. This case has made a more enduring impression because of its association with a retroverted uterus, with a subacute pelvic inflammation, and with the recurring abdominal pain and nausea. I have already so fully described it that I may merely add, that the pain in the *right* ovary is constant, and sometimes conveys the impression of dragging; the ovary is enlarged and tender, menstruation is insufficient in quantity and attended with much distress, and there is a general condition of great malaise. No local treatment of the uterus, whether of replacement or of internal medication, has given the slightest relief. Absolute rest, electricity, massage, and full feeding, have accomplished something, but the least departure from so strict a regimen sets up the old train of symptoms. Ergot with bromide of potassium, chloride of gold and sodium, the alternative treatment with mercury, and counter-irritation have all been equally unavailing, though a fair and honest trial was given to each. The fact seems to me to be clearly demonstrated that the uterine displacement has nothing to do with the distressing symptoms; that the retroversion and oöphoritis are entirely distinct maladies, each characterized by peculiar phenomena and each calling for separate treatment. While it may be an error to postpone an operation for the removal of the uterine appendages until the patient is worn out with her sufferings, it is a very natural timidity to

shrink from assuming so grave a responsibility, especially in the case of those within the home circle.

At the suggestion of Dr. P. J. Murphy, of this city, I have been induced to make a trial of rectal suppositories of one-quarter of a grain of *iodoform*, combined with a small quantity of the alcoholic extract of *belladonna*, one of these to be used three times a day. In three instances under my own observation, including the case referred to, these suppositories have given me more satisfying results and better grounded hopes of future alleviation than anything else that I know of. Absence from the marital embrace, with proper hygienic and dietetic rules, must be enforced rigidly. The alleviative and sedative properties of *iodoform* are well known, and in no other disease are its properties brought out so clearly.

BORO-CITRATE OF MAGNESIA FOR PHOSPHATIC INCRUSTATION OF URETHRA AFTER LITHOTOMY.

By S. S. KAHN, M.D.,

SAN FRANCISCO, CAL.

PATRICK R—, aged four years and six months, became a patient of mine on May 8th last. The symptoms of his affection, as described by his mother, were severe pain on micturition, with occasional stoppage of the stream, when his agony would be intense. When he was but nine months old the symptoms first began, and had continued uninterruptedly ever since. A number of physicians had at different times been consulted, none of whom seemed to recognize the true nature of the disease. At no time had any vesical examination ever been made.

In appearance the child was pale and somewhat emaciated. The prepuce was long from constant rubbing. A small-sized silver catheter introduced into the bladder almost immediately detected the stone. It lay to the left of the median line, was not movable, and seemed approximately to be about an inch in diameter.

Careful inquiry into the history of the case presented no ascribable cause. The father of the child was of very dissipated habits. The mother was stout and robust. They had had in all eight children, of whom but three were living. The eldest of these was of a strumous tendency, I having removed, a week or two previous, two lymphatic tumors from the neck. Those of the children who died showed the same tendency.

On May 12th I performed a median lithotomy, without any accident, and with but little trouble dilating the urethra and neck of the bladder. My finger in the bladder detected the stone, which was rough and knobbed, adherent to the vesical wall; the separation was easy. After some delay I succeeded in engaging it in the grasp of the forceps, and extracting it through the perineal opening. Hemorrhage during the operation was slight. After the extraction of the calculus the bladder was carefully searched, but no other stone or fragment discovered. Before leaving the patient the bladder was thoroughly washed with a weak solution of carbolic acid.

The stone had the knobbed appearance of a mulberry calculus, but on examination it was found to be phosphatic in character, with a small lithic acid nucleus. It was of an irregular cylindrical shape, about one inch in length and five-eighths of an inch in diameter. Its weight was one hundred grains.

Reaction after the operation was excellent. There was very little fever, and within two days it began to regain control over the bladder. On the third day some few drops of urine emerged from the meatus. On the fifth day fully half passed through the urethra, and it could retain water for two or three hours at a time. During all this time the perineal wound was repeatedly irrigated with a two per cent. solution of carbolic acid.

Sixteen days after the operation the patient was up

and about, the wound in the perineum had entirely healed, and urine passed through the urethra freely and without pain.

Four days later the boy was brought to my office in terrible agony, suffering from complete retention of urine. I immediately administered chloroform, for the child struggled too violently to admit of a careful examination otherwise. The penis was erect and much swollen. All along the track of the urethra could be felt little hard nodules. The endeavor to introduce a silver catheter into the bladder was unsuccessful. Even an elastic catheter could not penetrate beyond the beginning of the scrotal portion of the canal, where the largest concretion was located. The wall of the urethra was unevenly coated with this gritty deposit up to within three-fourths of an inch from the meatus. It was firmly adherent and could only with difficulty be scraped off.

Examining the perineal wound, I found that there was still a very small fistula left, through which I introduced a probe, which finally passed into the bladder. By moving this about the size of the fistula was enlarged, and when the probe was withdrawn, there was a copious flow of urine. During the passage of the probe through the prostatic urethra, the same gritty sensations were detected as before described. A hard-rubber catheter was then introduced into the bladder, tied in, and the patient sent home to return the next morning, when I proposed taking measures to relieve the obstruction.

The following day the child was again chloroformed. During the previous night the catheter had slipped out of the perineal opening, but it was easy to reinsert it. This I did, and injected through the catheter about two ounces of a one per cent. solution of the boro-citrate of magnesia. This I also injected into the meatus, but it did not penetrate far. I removed the catheter, as the fistula was sufficiently patent to allow of a free escape of the urine. I ordered the internal administration of a teaspoonful of this solution every hour. About eight hours after this procedure the child, in attempting to pass water, after a great effort accompanied with intense pain, passed through the urethra a quantity of this calculus material, about the size and double the thickness of a five-cent piece. Its consistency was like putty. Immediately after this the flow of urine was comparatively easy, although still attended with pain. His condition, however, was much relieved, and he slept soundly and well.

At the next visit the introduction of a silver catheter into the bladder was an easy task. Deep in the urethra there were still gritty points to be felt, but the pendulous urethra seemed clear, the perineal opening had again closed up. The bladder was once more injected through the silver catheter, and the internal administration of the drug continued. That night he passed a piece about the size and shape of a small bean. Subsequent examination revealed the fact that the canal was now free throughout its entire extent; the urine was clear, passed freely, and without the slightest pain. After this there was no further trouble, the child continued to take the medicine internally, but there were no further evidences of phosphatic deposit. It is now fully eight months since this complication occurred, but there has been no relapse and the patient has gained both health and strength.

It was not for the purpose of presenting the operation itself that this article was written, but to point out the oddity and the rarity of the complication that resulted. A careful search through the literature of the subject presents the most meagre details. The surgical authorities in common practical use make absolutely no mention of it. One German work refers to the possibility of the occurrence of incrustation of the urethra after operations for stone, but that it is very rare; and then dismisses the subject without one word as to prognosis or treatment.

Sir Henry Thompson speaks of an incrustation of the perineal wound, and this when slight to be treated with

hip baths or washing with a warm acidulated solution. Once or twice he has found it so thickly deposited that he was compelled to remove it with the forceps. In one case only it coated the whole track of the wound from the perineum to the neck of the bladder itself, and was crushed by him before the end of the fourth week. The wound was four months in healing. In my case, with the solvent or softening agent employed, the urethral tract was cleared in two days, the perineal wound closed up again the following day, and no further trouble ensued. A comparison of the two cases, methods of treatment, and results, is both interesting and instructive.

The possibility of dissolving urinary concretions within the living passages is a question of practical interest, especially as to the possibility of affecting renal calculi. Upon this subject many investigations have been made and varying opinions expressed by Mevet, Civiale, Rees, Roberts, and many others. In an exhaustive review of the subject, published in the "Medico-Chirurgical Transactions" of London, vol. xiii., 1865, Roberts enunciates the principles upon which the solvent treatment of stone should be carried out, declaring that while no new solvent agent had been discovered, they had arrived at a better application of treatment which had long been known in principle, but which had forfeited the confidence of the profession by the faulty manner in which it had been carried out, and its employment in cases where it was sure to fail. In the lithic acid diathesis, the alkaline treatment is emphatically recommended, particularly in limiting the size of the stone when once formed.

Dr. Koehler, in the *Berliner Klinische Wochenschrift*, No. 44, 1879, recommended the boro-citrate of magnesia, and asserted it to be very effective in the dissolution of stone in the bladder and kidneys, as well as in the treatment of catarrh of the bladder. He states that he has left a piece of uric acid calculus in the solution of the boro-citrate of magnesia, and found it broken up at the end of eight days. Reference is made to its use, in 1868, by Bacher, whose formula for the preparation of this salt is given in Hager's "Handbuch der Pharmaceutischen Praxis" as follows: Calcined magnesia, 30 grms.; boric acid, 100 grms.; distilled water, 10 grms. To this mixture is to be added 30 grms. of hydrochloric acid, C. P., and then sufficient alcohol to make it into a fluid paste, and to this add 60 grms. of citric acid. After the alcohol evaporates, this is to be pulverized. For use a one per cent. solution is to be prescribed and freely administered.

EXTIRPATION OF CANCER OF THE FACE, INVOLVING INFERIOR MAXILLARY BONE, FLOOR OF THE MOUTH (RIGHT SIDE), SUBMAXILLARY AND PAROTID GLANDS.

By G. WACKERHAGEN, M.D.,
BROOKLYN, N. Y.

PATRICK S—, fifty-five years of age; farmer; born in Ireland, consulted me on the 6th of December last in reference to a tumor situated over the middle of the right lower jaw. He was suffering great pain from the growth, but otherwise seemed to be in good health, excepting that he had a very feeble pulse. He appeared to be anxious that some operation should be performed, as the tumor was rapidly increasing in size, and he found great difficulty in taking nourishment.

Upon examination I found the most prominent portion of the growth circular in shape, and about one and a half inch in diameter, with ulcerated surface. The remainder involved the inferior maxillary bone, right floor of the mouth, and the submaxillary and parotid glands.

After explaining to him the danger attending so formidable an operation, and the probability of its return, I told him that I would consult with his physician, Dr. Alex. J. Rooney, which I did on the following day.

Dr. Rooney informed me that he had known the patient

several years, and that his general health had always been good. Three years ago he had attended him in an attack of double pneumonia; and two years ago he had removed an epithelial growth from his lower lip, when the wound healed readily. Last April Mr. Smith consulted him about a small tumor situated in the soft parts over the right lower jaw, which was well defined and movable. Upon examining the jaw, he discovered a decayed tooth, which he directed should be removed, and the tumor painted with tincture of iodine. Under this treatment the tumor disappeared, and did not return until about two months prior to his consulting me, when it commenced to grow rapidly, involving the surrounding tissues in all directions.

On December 7th I visited the patient at his home in New Utrecht, and finding him still anxious for relief, determined to operate on the following day. The gentlemen present and assisting at the operation were Drs. Spier, N. Ford, Rooney, and Silberman. Careful examination of the heart detected no organic trouble, though the pulse was remarkably feeble, but it improved during the administration of ether.

After placing a ligature upon the common carotid artery and internal jugular vein, I extended the incision upward around the lower portion of the tumor to the lower border of the inferior maxilla, following the lower border of this bone to its symphysis, and dividing the lower lip by a vertical incision. Commencing again at a point anterior to the tumor, the incision was carried above and around the upper and posterior portion, to the lower border of the jaw; thence around the angle and posterior border of the ramus, half-way to the condyle. The incision was then continued around the posterior and lower border of the tumor, to the point where I first started. The tumor was then detached from the inferior maxillary bone, which was found to be extensively involved.

The hemorrhage being quite profuse, in spite of the previous ligation, it was considered advisable at this point to perform tracheotomy, and continue the anæsthetic through a tampon. The instrument devised by Dr. A. Gerster was used for this purpose, and it worked admirably and proved a great convenience. It would seem impossible to improve upon this instrument, and for the information of those who may not have seen it, the accompanying illustration is introduced.

The diseased portion of the lower jaw was now removed by sawing and cutting through near the symphysis and at the angle. Following this the floor of the mouth (right side) including the submaxillary glands, and finally the parotid gland, with all connecting diseased tissue, were thoroughly removed. After the application of carbolic acid solution to the wound, the skin was drawn over and united, with only slight tension.

The patient speedily rallied from the operation, and on the third day was able to sit up. There were no unpleasant symptoms from the ligation of the vessels. The temperature did not reach above 101°, but the pulse was very feeble, and about 100. The nourishment consisted of beef tea, brandy, milk and eggs. On the fourth day he refused the quinine and stimulants, and the attendants stated that it was with great difficulty he could be prevailed upon to take any nourishment. By the ninth day he refused all food, and I passed a tube into the stomach and injected some beef-tea and brandy. The patient resisted so much that it became necessary to have him

held by the attendants. After this he took nourishment willingly, and in considerable quantity, until the twentieth day, when hemorrhage took place from the wound, the patient losing about a pint of blood before it was discovered. Styptic cotton was applied by one of the attendants, and a compress placed over the wound. Upon removing the compress next morning, I could not discover the origin of the hemorrhage. After my departure the patient again refused nourishment.

About a week after the operation, the integument covering the wound commenced to slough, so that the wound was entirely uncovered. The tracheal incision also refused to heal. During the entire period, there seemed to be scarcely any disposition toward granulation or healing; and the patient becoming more and more exhausted, died on January 1st, twenty-five days after the operation. The dressings consisted of carbolized oil, iodine, iodoform, and nitric acid solution, but they seemed to have little effect in promoting the healing process. Friends would not permit post mortem examination.

188 STATE STREET, BROOKLYN, February 7, 1883.

ON DR. SQUIBB'S RESOLUTIONS TO ABOLISH THE CODE OF ETHICS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.¹

By C. R. AGNEW, M.D.,

NEW YORK.

IF I understand the question before us, it is whether we will report for or against Dr. Squibb's resolutions, a question substantially presented, also, in the resolution of Dr. Gouley, "That when the Committee rises it shall report in favor of repealing the new code enacted by this Society in 1882."

I rise to oppose these resolutions and all similar ones, and to urge that when the Committee of the Whole rises to report to the Society, its report shall be against the repeal of the existing code.

A year ago, after mature deliberation and a free discussion, this Society, by more than a two-thirds vote, and in the exercise of its indisputable right, amended its by-laws so as to make them consistent with the laws of the State and public policy. It is true that various attempts have been made to promulgate the error that said action was hasty, imperfectly considered, and that a few "ambitious," "mercenary," and, not to say, unscrupulous members of the Society had brought it about; that "specialists" had been accomplishing their nefarious purposes through the force of ill-timed and badly directed energy. Such gratuitous allegations, however, have not stood for a moment the crucial tests of legitimate criticism or investigation, and may therefore be dismissed as unworthy of even this brief animadversion, much less the serious consideration of the medical profession of the country. In view of them one has only to recall a little history, and to draw comfort from its evidences of the triumph, even though it be sometimes slow, of liberty of conscience over prejudice, misrepresentation, and intolerance. Revisers, all down the pages of history, have had to endure hardship, and the only way for those who are called upon to do the work of revising is to live above the low level of the fear of their fellow-men, and not to be confused, diverted, or intimidated, even though the torch of persecution be brandished in their faces by those who assume to be the moral lights of the world, and the appointed guardians of its best interests.

"Zeal to promote the common good, whether it be by devising anything ourselves, or revising that which hath been labored by others, deserveth certainly much respect and esteem, but yet findeth but cold entertainment in the world. It is welcomed with suspicion instead of love, and with emulation instead of thanks, and if there be any hole left for cavil to enter (and cavil, if it do not

find a hole, will make it), it is sure to be misconstrued and in danger to become condemned. This will easily be granted by as many as know history, or have any experience. For, was there ever anything projected that savored in any way of newness or renewing, but the same endured many a storm of gainsaying and opposition?"

The revisers who unanimously reported the by-law, or code of 1882, framed it to be consistent with the Statutes of the State, especially the law of 1880. This Society adopted the Code by a very large vote without even a verbal amendment, after hours of animated discussion. Under this code or by-law, the medical profession of the State has prospered for a year, and might have gone on doing so for years to come, if it had not been for an agitation fomented by parties living outside of the limits of the State, largely aided, and no doubt on conscientious grounds, by the mover of the resolutions published and widely circulated in the "Ephemeris." The legitimate course would have been to have moved either to give up the charter of the Society, or to amend the State Statute of 1880.

It may be well for us to consider for a moment our position as a Society in relation to the State.

Whence do we get the right to be here in session? Indisputably through our charter from the State. No one but a legally qualified medical man has a right to be a member of this Society. It is nothing to the point to say that the diploma, or certified right to practise, comes from a medical school, and not directly from the State. In this State the law undertakes to regulate, by charter or otherwise, the powers which confer the right to practise, and the method is easy by which you may hold all who attempt to practise within the limits of the State to a strict legal accountability. It is true that this statute of 1880 regulating the practice of medicine is not all that it should be. It is not perfect, nor are the men who acquire rights under it. But it will be amended just as soon as the members of the medical profession cease to legislate for themselves in proscriptive codes, and join other public spirited citizens in inducing legislators to protect the people, as far as practicable, against medical incompetency. Whence do we, as a society, get the right to make medical codes and other by-laws? From the State through our charter. The New York State Statute of 1880 says, "Section 5. The degree of Doctor of Medicine lawfully conferred by any incorporated Medical College or University in this State shall be a license to practise physic and surgery within the State after the person to whom it is granted shall have complied with Section 2 of this act." Section 2 referred to, provides for registry in the County Clerk's office before commencing to practise, etc. Section 4 provides for the indorsing of the diplomas of persons coming to the State to practise, from without the State, by an incorporated university, medical college, or medical school, etc.

The revised Statutes of New York especially provide that every corporation, as such, has power "to make by-laws not inconsistent with any existing law for the management of its property, *the regulation of its affairs*, etc." And in accordance with this provision of the Statutes, the Medical Society of the State of New York has the right to make by-laws not inconsistent with the laws of the State. Kent says, "These corporate powers of legislation must be exercised reasonably, and in sound discretion, and strictly within the limits of the charter, and in perfect subordination to the constitution and general laws of the land and the rights dependent thereon." If you look at your charter you will find that whatever quality your by-laws, or codes, may have, they must, to be legal, and to have binding force upon your members, and punitive power, be "not inconsistent with the laws of the State."

Now, Mr. President, I put it to this society, are we prepared, even under the leadership of the eminent members, I do not call them conspirators, who have been sowing seeds of discord all through the year in the profes-

¹ Remarks made before the Medical Society of the State of New York, in Committee of the Whole, at its Annual Meeting, February 7, 1883.

sion and in this meeting, to array ourselves against the letter of the law and the policy of the State? Or, are we prepared to adopt the resolution to rise and report to the society to repeal the new code? Report to repeal the new code if you please. There is not much in the new code that I strongly desire to see retained. I am quite ready to abolish all but one or two clauses of it. I do wish, however, especially to see the clause retained which binds us all to acknowledge the public necessity for a "legally qualified practitioner." "Members of the Medical Society of the State of New York and of medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine." It is permissive, not mandatory. I wish to see the profession united to contend for that and to secure a higher and better standard of legal qualification.

Having a safe basis, and one on which legislators and the public are willing to aid us, we may as speedily as possible raise the standard of medical education, and express in amendments to the laws regulating the practice of medicine, a higher and higher ideal, and force schools and legislators to apply higher standards of fitness for practice. What I am opposed to here is the declared or implied purpose of the movers of both resolutions, namely: to re-enact the old code, and to throw on the profession, powerless to do the work, what belongs to medical schools and legislators.

One great defect in that old code was that it had come, in the process of time and growth of legislation, to be inconsistent with public policy in our State, and with its statutes. Would it not be grossly opposed to public policy and the letter of the law of the State to attempt, by any code or by-law of our making, to strip a fellow-citizen of a right which the State had conferred upon him: a right identical with that in the exercise of which we are authorized to be here to-night as duly qualified medical men?

The man whom the State has enfranchised this society cannot disfranchise. The medical man whom the State has pronounced to be a legally qualified practitioner, this chartered State Society cannot disfranchise, however much we may despise him or refrain from social communion or fellowship with him. We cannot discipline a member of our society if his conduct is in conformity with the law of the State.

Pass Dr. Squibb's or Dr. Gouley's resolutions, attempt by your vote to re-enact the old code, and you take action which will certainly be decided to be against public policy, and your action in making the by-law proposed inconsistent with the laws of the State. I here quote from a paper by Prof. D. R. Jaques, Professor of Municipal Law, University of New York:

"What is the Code of Ethics? What is the power of the State Society to enact one, or to legislate on any subject? What are the relations of the County Society to the State Society?"

"The State Society and each county society are *distinct corporations*, each with power to acquire and hold property; each with an organization of its own. The State Society is composed of certain permanent members, whom it selects in a certain proportion to the other members, and of members elected periodically. The act of 1813 speaks of them as members, not *delegates*. The State Society is not so much a representative body as a distinct and corporate board of control. The suggestion that the members elected by the county societies must vote as *instructed* by them is untenable. A doubtful principle in any case, it would convert the State Society into a *federal* organization, and would, in effect, require the members to vote *by counties*. In this way rules might be adopted which were disapproved by a large majority of the practitioners of the whole State belonging to the county societies. Moreover, who, it may be asked, are to instruct the *permanent* members?"

¹ See case of The State and relator Gray against Medical Society of the County of Erie, 24 Barbour.

"*Instruction* makes the delegate a mere messenger to carry the conclusions of the County to the State Society; but the members of the State Society are corporators of a distinct body, and go to its meetings to form, receive, and adopt conclusions as the result of views gathered from all sections.

"But the Statutes are conclusive on this point. They require that, in *all* cases, the rules and regulations of the county medical societies shall receive the *sanction of the State medical societies*, and the act of 1866 (chap. 445) applies this restriction to the homœopathic county societies as well. Now, if the county societies may instruct the members they send to the State Society, a majority of the counties could always control the State Society, which would be its mere creature and mouthpiece; whereas the act of 1813, in terms declares that the 'by-laws, rules and regulations' of the county societies shall not be 'repugnant' to those of the State Society.

"The rules of the Code of Ethics are *by laws*. Their force and effect are the force and effect they have as *by-laws*. The authority to adopt the old rule and the new rule of consultations must be found in the power given by statute to adopt by-laws and rules. The act of 1813 and the act of 1866 are explicit in requiring that the by-laws, rules and regulations of the State Society shall not be 'inconsistent' with the *laws of the State*. There may be an '*inconsistency*' which is not a direct violation of the law; but it is believed that the old rule is contrary to both the spirit and letter of the law, as it is contrary to the dictates of a broad and true humanity and the interests of medical science.

"It is not consistent with the *letter* of the Statutes which prescribe the qualifications of practitioners. It says, in effect, that the employment of physicians whom the law has sent into the community and pronounced qualified, thereby inducing the ignorant and the unwary to entrust them with their lives, shall be punished by deprivation of all benefit from the counsels of enlightened physicians. Will the law allow patients to be *punished* for employing those the law pronounces qualified?"

"But there is another consideration equally serious: The rule in question is the action of an organized body of men. It is the act of combination. The men thus combining are considered by many—and consider themselves—the most competent practitioners, the *only* fully qualified practitioners of the State. By adopting this rule, they *combine* to deprive the community of the best advice to be had in cases of sickness. Such a combination is against common law, and the provisions of the statute as well (Penal Code, Section 168). It is a conspiracy against the public health."

What are we to do then, Mr. President? For the present keep the code as it is. After we shall have defeated the attempts in this Society to lead us to rebel against public policy and the law of the State by re-enacting the old code, it will be time enough to say what we may do to amend the existing code. We shall be ready for that question in due season. We have not lowered our flag to any "ism," nor do we propose to.

"There is probably no one thing which man, considered collectively, grants less willingly to his fellow-man than liberty. Nine-tenths of all the wars which have desolated the earth, and no small part of all the ills that have afflicted humanity since the race began, have been due to a denial on the one hand, and an attempt to gain possession on the other, of those attributes of freedom which modern thought is coming to regard as among the inborn, inherent, and inalienable rights of every individual. And still the struggle goes on. Liberty of the person, liberty of belief and worship, liberty of speech and press, and liberty to have a voice in the choice of rulers and forms of government." I would also add liberty of medical consultations, "are still privileges denied to no small part of mankind; and any extension of liberty in these respects, in the future as in the past, will probably be conditioned upon long-continued, desperate

efforts and upon the payment in blood treasure, and suffering of large price. D. A. WELLS."

Charles O'Connor, the great jurist, in a recent letter to your speaker says, the "general doctrine of emancipation from every unnecessary restraint upon individual liberty in action or pursuit which forms the basis of the argument" (referring to the speaker's "Limits of Medical Ethics"), "has long had me for a disciple."

After we shall have defeated the attempts to re-enact the old code, let us return to our counties determined to carry into effect the laws we have against illegal practitioners, and to make the laws better. How many counties, represented here, have done their duty in this matter? New York County has endeavored strenuously to do its duty. Twenty-seven illegal practitioners have been arraigned in New York City during the past year, and twenty-five of the number have been convicted and punished. And at this moment charges are being pressed against a medical college there with good prospect of convicting its managers of illegal methods of granting diplomas.

But the question is pertinent, What are we doing individually for higher medical education? How many public-spirited men have we attempted to enlist in the cause of medical education in our respective counties? How much have we done to advance the interests of our Medical Alma Mater to give it the means to make its diplomas more valuable? How much have we done individually to change the character of proprietary medical schools, and to secure for them adequate funds and a more thorough and severe curriculum?

When we shall have begun even to consider honestly these and kindred questions, we will soon see the standard of medical education and of the legally qualified doctor rise, and the petty questions of schools and "isms" will, like other ephemeral issues, vanish or become despicable.

As regards error in medicine, what Thomas Jefferson said in another field is indisputably true here also. "Error of opinion ceases to be dangerous when reason is left to combat it." Leave members of a liberal profession free to go as advocates of the truth wherever called, and only restrained by the rules of common decency, legality, and prudence, and error will be less arrogant and dominant, and the dupes of error less numerous and more quickly rescued.

Progress of Medical Science.

THE TREATMENT OF PELVIC ABSCESS.—Dr. Tait treats this troublesome affection in the following way: He makes an abdominal incision, opens and empties the abscess, stitches the two wounds together, and secures drainage of the abscess cavity. The result has been most satisfactory, as twenty-two of his twenty-four cases were completely cured, and another is nearly well and improving, while in only one did the wound fail to heal, and the patient died of phthisis pulmonum, which was suspected when the operation was performed. Under the old methods of treatment, he says that more than one-half the cases were not cured, but either died or led an invalid life by reason of suppurating sinuses.—*British Medical Journal*, February 17, 1883.

TRANSFUSION OF PURE WATER.—Dr. Coates (*London Lancet*) reports a case of transfusion of pure water, warmed to the proper degree. The patient was a primipara, twenty-seven years of age. The cause of collapse was an alarming hemorrhage on the ninth day after childbirth. Some twenty-two ounces of water were allowed to enter the median cephalic vein through a Jennings siphon. The result was striking, and convalescence speedy.

CONGENITAL SARCOMA OF THE LOWER JAW.—Dr. Arkövy narrates the case of an infant, which was born with

a tumor of the lower jaw. The growth was about the size of a walnut, and on microscopical examination proved to be a large-celled sarcoma. Congenital neoplasms of this kind are known to be exceedingly rare. Thus Holmes's "Surgical Diseases of Children" mentions only two similar cases.—*Orvosi Hetilap*, February 4, 1883.

IMPREGNATION BEFORE THE MENSTRUAL EPOCH.—Mrs. P. J.—, born March 10, 1842, married December 24, 1854, making her age at marriage twelve years, nine months, and fourteen days. Was fully developed, but breasts were small and she had never menstruated. On the 9th of September following she was delivered of a well-developed child; time of gestation eight months and fifteen days. One month after delivery she menstruated for the first time, which lasted seven days.

Menstrual function was absent from this time until after the birth of the second child, which was born October 16, 1856, one year, one month, and seven days after that of the first.

From this date menstruation has been regular until about fifteen months ago, when it suddenly ceased and has not since returned. Her general health has been good. She was married three times and had five children. In 1862 had a miscarriage. At no time was the menstrual flow profuse.—*N. O. Med. and Surg. Jour.*

MULTIPLE LYMPHADENOMA OF THE CONJUNCTIVA.—Dr. Goldzieher, of Buda-Pesth, Hungary, who some time ago described a case of lymphadenoma of the conjunctiva (see *MEDICAL RECORD*, February 10, 1883), at a recent meeting of the Medical Society of Buda-Pesth, showed a patient, aged twenty-six, from whose left eye he had removed a portion of the ocular conjunctiva, including several milium nodules. Some of these were yellow, others grayish and translucent. Under the microscope they exhibited the structure of lymph-follicles with giant cells, but did not show Koch's bacilli. The wound healed kindly, but soon afterward a recurrence of the disease took place. Goldzieher is inclined to think that those cases which have been recorded as tuberculosis of the conjunctiva with caseous degeneration, were, like the present one, cases of lymphadenoma.—*Orvosi Hetilap*, February 4, 1883.

GASTRO-ENTEROSTOMY.—Dr. Fischer, of Strasburg, describes, in the *Deutsche Zeitschrift für Chirurgie*, a remarkable abdominal operation. In 1881 Freund removed a fibroid uterus from a woman, aged thirty. Last May this unfortunate patient, who appears to have been predestined to be a victim to abdominal disease, was found, by Dr. Fischer, to be suffering, according to his diagnosis, from carcinoma of the pylorus. Lücke determined to attempt resection of that part of the alimentary canal. From May 13, 1882, to May 25, the stomach was washed out every day, and on the 25th, after an enema had also been administered, the operation was commenced, without spray. The parts were exposed by a free incision, but resection was found to be impracticable, owing to extensive adhesions between the pylorus and the neighboring structures, especially the pancreas. The pylorus was therefore laid open and the aperture united to the abdominal wound, as in gastrostomy. The opening left in the wound was dressed with iodoform, and covered in with thymol-gauze. After the operation the patient did well; the temperature rose but little above normal, and she was discharged in thirty-seven days. Since then she has enjoyed very fair health, being free from attacks of vomiting, and can easily digest light, nutritious food.—*British Medical Journal*.

THE CLINICAL SOCIETY OF LONDON has appointed a committee for the purpose of inquiring into the results of the treatment of spina biida by injection. Circulars have been printed and sent to all the registered members of the profession in the British Islands.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 31, 1883.

STATE EXAMINATIONS IN GREAT BRITAIN.

THE chief subject of medical interest in Great Britain is the proposed new Medical Act, which is expected to come before Parliament for a second reading in the course of the next few days.

The pretty general opinion in London seems to be that the act is a good one. How the different licensing bodies of the United Kingdom will receive it is another matter.

Practically, the new bill, if it should pass and become law, will supersede most of the nineteen examining bodies now in existence. It is proposed to hold a State examination in each of the three divisions of the United Kingdom, and to admit no one to the register until he has passed this examination. By this means all students will be compelled to pass an examination in surgery, obstetrics, and medicine before being admitted to practice. Until a few years ago, the College of Surgeons did not examine in obstetrics for its membership examination, but only required a certificate of attendance on ten cases of labor. Their examinations have lately been extended, but even now there is no *clinical* examination in medicine, and no examinations at all in forensic medicine or chemistry, although courses of lectures must have been attended in these subjects.

Similarly, the Society of Apothecaries holds no examination in surgery, though lately the examiners in medicine have wandered somewhat into the region of surgery in their questions. The examination in anatomy is chiefly confined to regional anatomy, and does not comprise examinations on dissections. These anomalies will, it is to be expected, soon disappear.

All the British examining bodies require four years to be spent in study, of which period *at least* three winter sessions (of six months each), and two summer sessions (of three months each), must be passed at a medical school.

The examinations for the M.R.C.S. and L.S.A. are both of them sufficiently stringent so far as they go. The defect has consisted in granting a diploma which practically allows practice in all branches without examining in all.

The new act will also create a reformed Medical Council to which will be handed over the funds accumulated by the present one. It is to be hoped that the new council will do more useful work for the profession than

the present one has done. Most of its income has been devoted to salarizing the members, who hold an annual sitting which begins and ends in—talk! The present council has little power, and has made itself the laughing-stock of our professional cousins.

PNEUMONIA IN NEW YORK AND ITS TREATMENT.

CONSIDERABLE has been said of late regarding an alleged unusual prevalence of pneumonia in New York, and some attempts have been made to create a sensation over the matter. As will be seen by the accompanying table the mortality from pneumonia during the past few months has been somewhat greater than it was a year ago. For example: in the month of March, 1882, the weekly mortality from this cause varied between 97 and 111; in the corresponding month of the present year it has ranged between 110 and 128. For the two preceding months of 1883 the weekly mortality has also been greater. We must infer, therefore, that there is either more pneumonia at present than usual or it is of a more malignant type. At the same time the number of cases cannot be very excessive—certainly not enough so to cause alarm. A somewhat vague estimate of the number of cases occurring weekly might be made, based upon the probable per cent. of deaths from pneumonia. This per cent. varies between 2 and 33, but perhaps a mortality ratio of 15 per 100 would not be far out of the way. This would make the weekly number of cases at present about eight hundred.

Along with the increase in mortality from pneumonia there has been a slight increase in the mortality from phthisis, while that from bronchitis is not greater than it was a year ago. Despite the slight increase shown above, the mortality rate of the city is considerably lower than it was in the winter of 1881-82. It now ranges between 25 and 30 per 1,000, the number of deaths for the week ending March 25th being 763. During the month of March, 1882, the mortality reached as high as 814 per week, the increase being due to an excessive prevalence of zymotic diseases.

In the management of pneumonia, New York physicians, in accordance with the prevalent American teachings, adopt the principle that there is no *special* treatment for the disease. In most cases, rest, pure air, careful attention to nourishment, and, toward the close, some stimulants, are generally all that is resorted to. A little morphine, or a hypnotic, and some external applications are often used. Cold water applications are, we believe, very universally condemned—as they should be. Tartar emetic, iodide of potash, bleeding, and even quinine, are special drugs whose regular use is now generally abandoned. Some physicians give aconite or veratrum at the beginning of the attack. The administration of sedative doses of calomel, toward the close of the fever's course, is a practice that is creeping into fashion. The results are sometimes brilliant, but not rarely are disappointing. Cardiac stimulants, cupping, bleeding, inhalations of oxygen, etc., are measures that have to be employed to relieve the dyspnea, exhaustion, and threatened heart-failure in serious cases.

THE PHYSICIAN AND HIS PROFESSIONAL SECRETS.

A SUIT involving the old question whether information obtained by a physician from a patient, orally or by observation, must be disclosed on the witness stand, has recently been tried before the Supreme Court of Missouri. The law in that State declares that a physician "shall be incompetent to testify concerning any information acquired by him from any patient whom he may be attending in a professional character, and which information was necessary to enable him to prescribe as a physician or operate as a surgeon." The court held in the case in question that it will not do, while the mouth of a physician is closed as to the talk of his patient, to open it as to knowledge acquired from his own diagnosis of the case.

It thus sustained the law and the principle underlying it, and the decision is an important one.

The law in the State of New York is very much like that in Missouri. In England, however, the highest legal authorities have decided that medical men enjoy no special privilege with regard to secrets of a professional nature.

Although this view may have a great weight of legal argument in its favor, it is not the one which the medical profession or the leading medical jurists advocate, and we are gratified to find that the medical, and as we believe, higher position, is gaining strength.

The single weak point in the laws of Missouri and of some other States, regarding this position, is that they do not sufficiently insure to citizens a high status for these medical men who are thus privileged to keep back evidence.

FALLING FROM GREAT HEIGHTS.

It has been asserted that a man falling from a great height dies before he reaches the ground, and we recently noticed this question discussed in a public journal.

The experience of an aeronautical party in the balloon Owl, which made a very rapid descent, during the fall of last year, at Dunmow, Essex, England, throws some light on this disputed subject.

The voyage being limited to time by the conditions of the contest in which the party in the car were engaged, a rapid descent became necessary. The valve was twice opened, and volumes of gas rushed out. The balloon fell plumb 1,300 feet in one minute and a quarter. They came to the ground with a thud which sent one of the occupants of the car limping for six weeks afterward, but none of his other three companions suffered from the severe bone-shaking. It is interesting to know that their breathing was not in the slightest degree affected by this rapid falling through the air. All appeared to be perfectly conscious, and as calm as men might be who had reason to fear that their next second might have been an eternal one.

We understand it is on record that one aeronaut fell from a car, a distance of sixty feet into a ploughed field, without loss of consciousness.

A WORD TO OUR STATE MEDICAL SOCIETIES.

WE have before us a large number of the "Transactions" of State Medical Societies. They are most suggestive volumes, like all things which are truly American. But perhaps the thing most strongly presented, after turning some of the pages, is the query whether or not our State Societies have any function as scientific medical bodies. It has been, we know, the fashion to decry State medical work, but unfortunately this fashion has had a solid basis, and criticism is still sadly needed. And as this work for the present year will soon begin, we may very properly assume the task of gentle criticism now.

One of the great needs of the societies in question has been efficient and experienced officers who understand what to do in order to get work out of a medical organization. All societies should have a practically, permanent executive officer, who should generally be the secretary. This officer, if supplied with a little money and a good deal of intelligent energy, could arrange definite programmes of scientific work, could solicit papers from men who know how to write, and could pre-arrange discussions. For experience has as yet failed to teach our brethren who attend State societies that the medical work is not actually done at the annual meetings, nor is it expected to be done. This work is to be finished before the sessions and simply reported on at the time of meeting. Experience has also failed to teach society managers that even debates are rarely satisfactory and useful unless some previous thought has been specially given to the subject in hand. All these things a good officer could and should attend to.

The practice has been growing in some societies of having special reports upon various branches of medicine. These reports are merely summaries, taken from medical journals, and contain no originality. They are a form of literary work which should not be presented at

meetings of medical societies. The same reports and better ones are found in a dozen medical periodicals, and it is first-hand work which such large bodies, as our State medical organizations are, should call out.

With a competent executive to arrange for real work, a society may, with a clear conscience, indulge in social relaxations. We believe in the usefulness of this feature, promoting, as it does, mutual acquaintance and good-fellowship. Happily our societies are already quite beyond the need of criticism or advice in their provisions for this part of the proceedings.

We trust that the presidents of our State societies, who will now so soon be delivering their "inaugurals" and "annuals," will temper their eloquence with some practical suggestions. We have heard quite enough, for example, in annual addresses of the scope and beneficence of "preventive medicine." We respectfully request that this topic, which has been the mainstay of presidential eloquence for several years, be allowed a temporary repose. Let the presidents urge the adoption of systematic methods of work, the securing more and better papers, the encouragement of critical discussion. In this way there may in time be some good work done and good volumes published. At present the majority of State Medical "Transactions" are worth little more than the paper on which they are printed.

THE ABSTRACTS.

THIS class of powdered drugs introduced in the new Pharmacopoeia, claims some attention from physicians. It is introduced, we are told, in order "to supply a demand for dry-powdered extracts." These abstracts are just twice the strength of the crude drug, or about twice the strength of the fluid extracts.

The chief objection to them is, according to *Ephemeris*, that they require a troublesome, expensive, and hurtful process to effect a little in the way of concentration, condensation, and convenience.

In order to have them of uniform strength, many are made much weaker than they might have been, and are consequently bulky and inconvenient.

A list of eleven drugs is given of which abstracts are made. For the information of our readers we append the list: Valerian, podophyllin, nux vomica, jalap, ignatia, hyoscyamus, digitalis, belladonna, aconite, senega, conii.

In an analysis and description of these drugs given by the authority above quoted, we are told that there are only two of them, conium and senega, which have any especial advantage over the crude drug or extracts.

UTERINE DYSPEPSIA.

In an article upon this subject in the *Prager Medicinische Wochenschrift*, December 20, 1882, Dr. E. H. Kisch remarks upon the relationship existing in health between the stomach and the uterus. He states that while normally the reaction of the stomach becomes neutral in five to seven hours after a meal, during menstruation it remains constantly acid. Not all affections of the female sexual organs give rise to dyspepsia, but only those of the uterus itself, and of these may be excluded all superficial erosions and affections of the mucous mem-

brane, thus leaving as causes only the structural changes of the organ, versions, flexions, subinvolution, deep follicular and cancerous ulcerations, and similar conditions. The most frequent cause of digestive disturbance he finds to be retroflexion. The symptoms vary much in intensity, sometimes, however, they assume a most threatening severity. The appetite is capricious, the tongue is but slightly coated. There is often pain in the epigastrium, with sour eructations and heartburn. Sometimes there is vomiting after each meal, together with constipation and flatulence.

Sympathetic disturbances are common, such as palpitation of the heart, neuralgia, melancholia, etc. The affection is to be distinguished from gastric catarrh, ulcer of the stomach, and simple nervous dyspepsia. This is to be determined by attention to the symptoms peculiar to each of these conditions, but especially, and sometimes only, by the results of treatment. With the improvement in the affection of the uterus the dyspeptic symptoms subside. Hence all curative efforts are to be directed especially against the abnormal condition of the uterus. Certain mineral waters are often of great value, especially those containing sulphate of sodium. The author concludes by urging the necessity of a uterine examination in all cases of obstinate dyspepsia occurring in females.

A STATE CHEMIST.

FOLLOWING the example of some European countries, it has been recommended to the Medico-Legal Society that the State of New York create the office of a State chemist. The person holding this office is to have charge of a laboratory suitably furnished. His duties should be to make proper and careful analyses in all cases of poisoning, etc., where such analyses are needed. In this way the State and the accused would be sure of having examinations made by experts who were non-partisan and competent.

The idea at once arises that, under our present political system, the officer thus appointed might very likely be more of a "statesman" than a chemist. If we are to have a State chemist also, why not a State expert in insanity and other branches? The scheme appears to have no inherent objections, but it would be difficult to carry it out satisfactorily.

THE ELECTION OF NEW YORK COUNTY DELEGATES.

THREE new delegates were elected at the meeting of the County Medical Society, March 26th. The occasion was taken to bring up again the question of codes. The three delegates, elected by a vote of 94 to 71, represent the old code element. This result was saluted as a great victory. We trust that those who so announce it will have the fairness to add some of the accompanying facts. The vote was obtained by means of systematic canvassing and a preliminary caucus. Printed ballots were supplied and all the machinery for securing the desired end was put in action. The other side, which has already polled twice the number of votes cast at the last meeting, was taken by surprise and made little preparation for so vigorous a campaign.

The result will have the effect of silencing those who

have been charging the new code and no-code party with using political methods and of packing meetings.

So far as this election goes, the vote of the State Medical Society remains substantially unchanged, being made by it 102 to 106.

It is a noticeable fact that out of the 2,500 physicians in the city, and 900 in the County Society, only about 200 can be wrought up to enough interest in the code to vote upon it.

We are glad to observe that the battle in the city here is still in the main a good-natured one and it should be kept so. We have plenty of mud thrown in from outside.

SPINA'S ATTACK ON KOCH.

DR. ARNOLD SPINA, of Vienna, one of Professor Stricker's assistants, has published a brochure in which he strongly attacks some of the claims made by Koch. Dr. F. E. Saltler (*Cincinnati Lancet and Clinic*) gives the following summary of the points which are made:

First.—Dr. Spina denies the statements of Koch and Ehrlich, that solutions of the aniline dyes must react alkaline in order to stain the so-called bacillus tuberculosis, and also that acids and aqueous solutions of vesusin do not enter the bacilli.

Second.—He denies that bacteria, which stand in no causal relations to tuberculosis, react in a different way with coloring matter from the bacilli found by Koch.

Third.—He denies the statement of Koch that the bacilli of tuberculosis occur constantly in the tuberculous organs of man. He found that this statement was too far reaching, and in many cases examined he never found any bacilli. As regards the bacilli in sputa, his results agree essentially with those of Koch.

Fourth.—He was never able to find bacilli in the tubercles which stood in no connection with the open air—the serous membranes of the body. He says “I have examined about one hundred and fifty mesenteric and omental tubercles, in the most various stages of their development, according to Koch's and Ehrlich's method, and found bacilli in *not one* case.”

Fifth.—He also criticises the insulation experiments made by Koch with purified bacilli, and says that the specific character of tuberculosis has not been proved by them. He calls attention to the history of inoculation experiments; the conflicting results, the negative and positive results of inoculations with tuberculous matter and indifferent substances, and also gives the results he obtained by inoculations with purified bacilli.

Sixth.—He concludes by saying that the bacilli of tuberculosis are the result, not the cause of the disease.

Dr. Spina's paper is critical and aggressive rather than judicial. His view that the infection of animals by tubercle has not yet been proved; in other words, that tuberculosis is not an infectious disease, is contrary to the general tendency of pathological opinion at present.

A SWISS HOSPITAL IN NEW YORK.—It is proposed to erect a Swiss Hospital and Home in this city. The enterprise is under the management of the Swiss Benevolent Society, which already has five thousand dollars for the object. The Swiss in New York number between twelve and fifteen thousand.

News of the Week.

A LAW TO LEGALIZE DISSECTION in Colorado has recently passed the Legislature.

AN EPIDEMIC OF SMALL-POX IN NEW ORLEANS.—Small-pox continues to increase in New Orleans. During the week ending March 24th the number of deaths from the disease was sixty-five, out of a total of one hundred and seventy-nine deaths.

NEW DELEGATES OF MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—At the stated meeting held the 26th inst., Drs. Charles Hitchcock, Charles A. Leale, and Charles S. Ward were elected delegates to fill the vacancies caused by the resignation of Drs. Laurence Johnson, David Webster, and Frank P. Foster, who were elected permanent members at the last meeting of the Medical Society of the State. The newly elected members are in favor of retaining the Code of the American Medical Association.

A GENEROUS ACT.—The *Louisville Medical News* publishes a list of the New York physicians who were active in sustaining the present code of ethics, and now impliedly recommends that the physicians of the South and West send no patients to these gentlemen, on the ground that they are dishonest, mercenary, and desirous of affiliating with and encouraging quackery.

AN ANNUAL ALUMNI PRIZE of one hundred dollars has been offered by the Alumni Association of the College of Physicians and Surgeons of Baltimore.

A CORONER'S VERDICT UPON A DOCTOR AND APOTHECARY.—The coroner's jury at Titusville, Pa., recently found that Leander Smith, of that place, came to his death by a dose of cyanide of potassium, which had been obtained for him by a physician, at a drug store temporarily in charge of an inexperienced clerk. They found the doctor guilty of criminal ignorance in ordering so poisonous a drug and directing its use in the manner he did, and they found the proprietors of the drug store culpably ignorant and guilty of keeping and selling drugs the nature of which they know nothing about, and guilty of employing an inexperienced druggist.

NO SCHOOL OF PHARMACY FOR WOMEN has been established at Louisville, Ky., as has been very generally reported.

TESTIMONIAL TO PROFESSOR ERICHSEN.—A bust of Professor Erichsen and a sum of money were presented to him a few weeks ago by a number of his pupils and admirers. The bust is deposited in the University College. Mr. Erichsen will use the money to found a prize for skill in operative surgery.

THE STATE PHARMACEUTICAL ASSOCIATIONS of the country meet this year as follows (*Pharmaceutical Record*): April 2d, Louisiana, at New Orleans; May 1st, Iowa, at Davenport; May 8th, Alabama, at Selma; May 15th, Virginia, at Norfolk; May 16th, Massachusetts, at Springfield; May 16th, New Jersey, at Orange; May 16th, Ohio, at Cleveland; May 16th, Kentucky, at Eminence; June 12th, New York, at Ithaca; June 12th, Pennsylvania, at Harrisburg.

STATUE TO PINEL.—Subscriptions are being made in Paris to erect a statue to Pinel. The sum of five thousand dollars has already been raised.

THE NEW YORK SKIN AND CANCER HOSPITAL.—The *Medical Herald*, of Louisville, Ky., says that voluntary contributions for the establishment of this hospital "are being solicited openly all over the country by a printed circular." The promoters are criticised for thus going abroad to beg.

SANITARY INSPECTOR OF SCHOOLS.—Dr. W. E. Griffiths has been appointed by Health Commissioner Raymond, of Brooklyn, Sanitary Inspector of Schools.

A NEW MEDICAL POET.—Dr. S. Weir Mitchell has recently had published a volume of poems entitled, "The Hill of the Stones, and other Poems." The work is highly spoken of. We welcome another medical man into the ranks of poesy; Esculapius was the son of Apollo.

PROPOSED STATE EXAMINATIONS IN GREAT BRITAIN.—There are in the United Kingdom nineteen examining bodies, no two of which agree exactly in the standard of their examinations. Some of them are very severe—notably those of the Universities of London and Cambridge; some are quite the reverse. Nevertheless, all boards now require four years study, and examine in medicine, surgery, and in midwifery before granting a diploma. The English College of Surgeons has recently extended its examinations, and even the Society of Apothecaries now gives some surgery in their final examination. All this, we learn, is to be changed, and a state examination of uniform standard instituted in each of the three divisions of the United Kingdom.

THE NEW HOSPITAL FOR SMALL-POX on North Brother's Island in this city is nearly completed. The old Riverside Hospital on Blackwell's Island will be used probably for other contagious diseases.

THE NEW YORK INFANT ASYLUM.—A medical board has recently been appointed for this institution, consisting of the following gentlemen: For the Sixty-first Street branch, Drs. J. Lewis Smith, George B. Fowler, *Diseases of Children*; Drs. C. L. Dana, Græme M. Hammond, *Mental and Nervous Diseases*; Drs. Paul F. Mundé, William M. Polk, J. Clarke Thomas, *Obstetrics*; Dr. O. D. Pomeroy, *Ophthalmic and Aural Diseases*; Dr. George M. Lefferts, *Diseases of the Throat*. For the Mount Vernon branch, Drs. George S. Conant, J. H. Ripley, *Diseases of Children*; Drs. W. R. Birdsall, W. J. Morton, *Mental and Nervous Diseases*; Dr. William F. Mittendorf, *Ophthalmic and Aural Diseases*; Dr. T. H. Bosworth, *Diseases of the Throat*.

For both branches: Dr. H. G. Piffard, *Dermatologist*; Dr. L. H. Sayre, *Orthopedist*; Dr. Cyrus Edson, Surgeon; Dr. A. N. Bell, *Sanitarian*; Drs. T. E. Satterthwaite, and William H. Welch, Curators and Pathologists.

REJECTED MEDICAL COLLEGES.—The following medical colleges are not recognized by the Illinois Board of Health: American Eclectic Medical College, Cincinnati, Ohio; American Health College, Cincinnati, Ohio; American University, Philadelphia, Pa.; College of Physicians and Surgeons, Buffalo, N. Y.; College of Physicians and Surgeons, Joplin, Mo.; Edinburgh Uni-

versity, Chicago, St. Louis, and elsewhere; Hygeio-Therapeutic College, Bergen Heights, N. J.; Eclectic Medical College of Pennsylvania (late issues); Joplin Medical College, Joplin, Mo.; Livingston University, Haddonfield, N. J.; New England University of Arts and Sciences, Boston, Mass., and Manchester, N. H.; Northwestern Medical College, St. Joseph, Mo.; Penn Medical University, Philadelphia, Pa.; Philadelphia University of Medicine and Surgery, Philadelphia, Pa.; Physio-Eclectic Medical College, Cincinnati, Ohio; Physio-Medical College, Cincinnati, Ohio (late issues); St. Louis Eclectic Medical College, St. Louis, Mo.; St. Louis Homœopathic Medical College, St. Louis, Mo. The list embraces eighteen names, and is short enough.

THE DUVAL PRIZE of the Paris Society of Surgery has been awarded to Dr. Desnos for an essay on "Lithotripsy in Prolonged Sitzings."

THE FOTHERGILL GOLD MEDAL for 1883 has been presented to Mr. Norman Perritt, L.R.C.P., for an essay on "The Operative Treatment of Intrathoracic Effusion."

THE NEW YORK COLLEGE OF PHARMACY held its annual banquet at Delmonico's March 27th. Dr. D. H. J. Menninger presided. Speeches were made by Rev. J. P. Newman, Hon. R. P. Flower, Dr. Walter De F. Day, Mr. D. C. Robbins, Professor Ewen McIntyre, and others. The ices were served in white pastry skulls.

THE MEDICAL ASSOCIATION OF GEORGIA meets at Athens on the third Wednesday in April.

AN ABORTIONIST ARRESTED.—One of the many creatures in this city who unblushingly traffic in foetal life was recently arrested and is likely to be punished. The cases in which sufficient evidence to convict is obtained, like the present, are unfortunately rare.

FREE LECTURES ON MATERIA MEDICA.—Dr. D. W. Prentiss is giving a course of free lectures on Materia Medica at the National Museum, Washington, D. C.

AN ANTI-VIVISECTION SOCIETY is to be organized in Philadelphia.

TYPHOID FEVER FROM MILK.—In a group of fifteen typhoid fever cases recently occurring in the northwestern part of the city, it has been found that all the patients used the milk from one herd of cows, one of which suffered from a herpetic eruption. This cow is watched and the use of its milk is prohibited. The sanitary condition of the houses inhabited by the persons who contracted the disease is excellent.

MEDICAL HOSPITALITY.—An entertainment fund has recently been endowed in the Philadelphia College of Physicians by Dr. S. Weir Mitchell. The income is to be used, under the direction of a standing committee, to defray the expenses of occasional receptions, at which refreshments suited to the dignified character of the Society are to be provided. It is proposed to issue invitations not only to members of the College and other physicians, but also to laymen who may be identified with the intellectual welfare of the city. In this city the New York Academy of Medicine formerly dispensed doughnuts, coffee, and sandwiches after the scientific labors were over. The practice has now, we believe, been given up.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 28, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

(Continued from p. 332.)

* SPINA-BIFIDA COMPLICATED WITH HYDROCEPHALUS.

DR. PUTNAM-JACOBI presented a specimen accompanied by the following history: The child was first seen at the dispensary at Mt. Sinai Hospital about a month after its birth, and then presented a tumor which occupied the entire region of the lumbar vertebrae, the posterior arches of which were evidently absent. The tumor was not covered by skin, but only by a semi-transparent membrane which was ulcerated at the time that she first saw the patient, and during the entire year which followed it continued in an ulcerated condition despite all the care given to it. The tumor was entirely incompressible, but pressure gave rise to no pain, and to no perceptible phenomena. The child was completely paralyzed in its lower extremities, and also had double talipes calcaneus. It exhibited no cerebral symptoms. The treatment was entirely expectant, consisting chiefly in emollient dressings and protection. At the time the child was seven months old its head began to enlarge, and the eyes showed the characteristic appearances of hydrocephalus. They were not protruded at all, but it was noticeable that rolling down of the eyeballs occurred simultaneously with enlargement of the head, thus showing that prominence of the eyeballs cannot be due to mechanical protrusion of the eyeballs from fluid in the orbit, but rather to paralysis of the superior rectus muscle, as suggested by Henoch. Emaciation began from this date. The child remained under observation five or six months, had occasional attacks of apparently cerebral hyperæmia, apparently suffered from headache, and finally died comatose in one of these attacks. The child had no convulsions. It seemed quite probable, on account of the paraplegia and the double talipes, that there might exist communication between the sac of the spina-bifida and the cerebral ventricles, accompanied with dilatation of the central canal of the spinal cord. At the autopsy, however, there was no trace of any such dilatation. A considerable quantity of fluid was found in the arachnoid cavity of the cord which communicated below with the cavity of the sac, and above, through the transverse fissure, with the subarachnoid cavity of the brain, but there was no dilatation of the central canal, and the sac did not communicate with it or with the cord at all. The sac lay against the posterior surface of the bodies of the lumbar vertebrae, from which the posterior arches were absent. The termination of the cauda equina was spread out on the lamina of the sac, which divided its cavity into several loculi. The brain exhibited an extensive dilatation of the lateral ventricles, the latter being filled with serum. There was no roughening of the ependyma, such as exists when ventricular effusion is due to leptomeningitis. The effusion, however, within the ventricle was not sufficient to compress the cerebral convolutions from within. There was no softening of the brain. Death seemed to have been due to gradual pressure within the ventricle without secondary encephalitis or softening. The intelligence of the child was perfectly preserved as far as could be ascertained, but at the time of its death the body was no larger than that of a child five or six months old.

DR. HEINEMAN referred to a case of spina-bifida in which the sac was nearly as large as an orange. In that instance there was double equino-varus with decided spastic contracture. The tumor was situated over the region of the cauda equina.

DR. WYETH referred to a case which came under his

observation at the Polyclinic, in which there was a very great variety of deformities—cleft palate, hare-lip, and with the others a double talipes varus on one side and valgus on the other. His belief was that in these cases the deformities were due to lack of development.

DR. PUTNAM-JACOBI remarked that the association of club foot with spina-bifida had been often noted, and it was remarkable that it was due in some instances to compression of the spinal cord.

DR. L. EMMETT HOLT presented a specimen of

GLIO-SARCOMA OF THE CEREBELLUM (SEE PAGE 342).

DR. WYETH asked if any examination was made of the semicircular canals or the petrous portion of the temporal bone.

DR. HOLT replied that there was not.

DR. WYETH thought it important that such an examination should have been made, as the same symptoms present in Dr. Holt's case might be produced by the affection known as Ménière's disease, which had been established to be due to disease of the semicircular canals, and that interference with the function of the semicircular canals is accompanied by lack of co-ordination.

DR. HOLT remarked that Nothnagel had made a very careful *résumé* of the literature of tumors of the cerebellum, and had reached the following conclusions:

First.—That they were unable to make any diagnosis positive of a lesion which affects the lateral lobes of the cerebellum.

Second.—That the main symptom is ataxia, and this is only present when there is destructive lesion affecting the vermiform process; that the ataxia symptomatic of cerebellar lesion is not like that of locomotor ataxia, but resembles that which exists in alcoholic poisoning.

In his specimen the lesion was limited almost entirely to the vermiform process and to the anterior lobes; the lateral lobes were healthy.

DR. PUTNAM-JACOBI remarked that if a tumor press upon the pons, convulsions might occur and complicate the case. She had seen one case of this kind which was rather an interesting combination of lesion and diagnosis. In a large number of cases of tumor of the cerebellum mentioned by Nothnagel, amaurosis was present.

DR. HOLT remarked that another symptom mentioned by Nothnagel is vertigo, but the presence of this symptom it was difficult to determine in so young a child as was the patient in the case reported.

DR. BIRDSALL remarked that the peculiar description of the ataxia given by Dr. Holt was typical of cerebellar disease, and that the case was extremely interesting with reference to location of the tumor in that region. With regard to disease of the semicircular canals producing certain symptoms, he believed it to be well established that the symptoms of Ménière's disease might depend upon disease of any part of the auditory tract, or disease from that portion back to the centres of the medulla oblongata, and possibly certain parts of the cerebellum from the same cause. The view which at one time held sway that only lesions of the labyrinth caused Ménière's disease he believed had been so modified that it was now generally admitted that disease in any part of the auditory tract might give rise to the symptoms present in that affection.

DR. W. T. BELFIELD was made member by invitation, and demonstrated to the society

THE BACILLUS OF LEPROSY AND THE PRACTICAL USE OF ABBÉ'S ILLUMINATOR.

The two points which he regarded as of special importance in order to demonstrate the presence of bacteria were, first, the use of aniline staining, and, second, the use of Abbé's illuminating apparatus. The peculiarity of the bacteria was that they retained aniline colors under conditions which deprived every other substance of the color. The effect of the illuminator was to obliterate refraction outlines, leaving the bacilli in the luminous field

where, by virtue of their retained color, they are distinctly and easily recognizable.

DR. WENDT was pleased to hear Dr. Belfield admit that in the present state of our knowledge concerning most of the bacteria, we could speak only of their association or coexistence with certain pathological conditions. Perhaps a relation of cause and effect would sooner or later become established. But at present evidence of this kind was still forthcoming. For this reason he thought that when Dr. Belfield had cited trichinosis as a similar example, he had not done justice to the fuller knowledge which we possessed of that subject. Dr. Wendt did not consider trichinosis analogous to the so-called bacterial diseases. For the natural history of the trichina spiralis was fully known, and its causal relationship to attacks of trichinosis did not admit of the slightest doubt. Not so with the bacteria, however, as Dr. Belfield himself had freely admitted.

DR. BELFIELD dissented entirely from the statement made by Dr. Wendt that a relation of cause and effect had been demonstrated between trichina and the clinical history of the disease known by the name of trichinosis, as we did not know much more with reference to the natural history of the parasite than was at the present time known concerning the natural history of the various forms of bacteria. It was known and established that a parasite occurred in the intestines and in various parts of the body, but where it came from originally we were in just the same doubt as in regard to the different varieties of bacillus, and that there was any demonstrative relation of cause and effect he was not willing to admit.

After some further discussion the Society went into executive session.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE OF MEDICINE.

Stated Meeting, March 20, 1883.

EDWARD G. JANEWAY, M.D., CHAIRMAN.

DR. V. P. GIBNEY reported

CASES OF POLIO-MYELITIS ANTERIOR.

CASE I.—*Affecting left leg and foot when fourteen months of age; right similarly, though not symmetrically affected five months later.*

Louis S—, aged sixteen months, was seen first on November 18, 1882, with an infantile paralysis of left leg. It was reported to be of two months' standing, but no further information concerning the attack was recorded.

There was no faradic response in the muscles of the leg, nor was there any to galvanism except in the extensor long. digitorum, where Ca. C. C. > An. C. C. (both weak).

An apparatus was applied, and he was temporarily discharged to report again when he had recovered from pertussis.

January 27, 1883.—He reports to-day for the first time since last note. No response to either current in the affected limb.

February 16th.—For a week or more a response to galvanic current has been obtained in both anterior and posterior tibial groups, A. C. C. > C. C. C., but it requires a fairly strong current. For the electrical notes recorded every few days, I am indebted to Dr. S. M. Taylor, of our hospital staff.

February 23d.—On Monday last (19th inst.), the patient refused to stand on right [affected] limb. He fell frequently, the limb having apparently lost all strength. This was mentioned by the mother on her previous visits, but no notice was taken of it. There was unquestionable degenerative reaction in anterior tibial group, where there was apparent loss of power on the 21st inst.

To-day the degenerative reaction—well marked—was

obtained in all muscles below gluteal region, except posterior tibial group.

February 28th.—Measurements. Right thigh, 9 $\frac{3}{4}$ —8 $\frac{3}{4}$ inches; left, 9—7 $\frac{1}{2}$; right calf, 6 $\frac{1}{2}$, left, 5 $\frac{3}{4}$ inches.

March 5th.—All the muscles of right limb react to a moderate faradic current, except anterior tibial group; also quadriceps extensor and the peronei are questionable. Degenerative reaction in anterior tibial (muscle). Response in quadriceps either normal or C. C. C. = A. C. C. The posterior tibial and posterior thigh group do not respond to the current which gives a response in above mentioned muscles.

March 7th.—Mother reports that yesterday the child would frequently cry out while at play with pain in the limbs. He often complained of the left as the right. He moves the right limb very freely under the stimulus of the current to-day. Can flex the foot and use the toes, using the anterior tibial group where there remains a A. C. C. > C. C. C. No response from nerve. Response to galvanic *nil* in other muscles, all of which react normally to faradism. Electrical treatment suspended for a week.

March 14th.—Is beginning to use the limb a little in standing. No electrical examination to-day.

March 20th.—Examined by Dr. Birdsall to-day with the following result: Right limb. Faradism. Peroneal (nerve) weakened. Primary reaction in anterior tibial group. Muscles. Slight primary in anterior and posterior tibial groups. Left limb. Peroneal. No reaction in either muscles or nerves.

A moderately strong galvanic current, over the peroneal nerve, right side, gives the normal reaction in the anterior tibial group.

Stimulation of the anterior and posterior tibial groups of muscles, right side, gives the normal response.

Typical degeneration reaction in the posterior group of muscles, and no response whatever in anterior tibial group to a strong current.

CASE II.—Thomas G—, aged five. Came to the Outdoor Department of the Hospital for Ruptured and Crippled on March 16, 1883, for the treatment of paralytic talipes.

The mother gave a history of an illness of three weeks dating from Thanksgiving Day of last year. He had considerable fever, and very marked hyperæsthesia of both limbs during this time. The pain in the limbs was the most prominent symptom. The loss of power was noticed in the beginning of his illness.

In a few weeks he began to use the limbs and was soon on his feet. The right limb has entirely recovered. There is one inch atrophy of left calf, one-half inch of instep. Marked coldness of surface and anæsthesia. There is a degenerative reaction in anterior and posterior tibial groups to the galvanic current. Peroneal group shows normal formula but exalted contractility. Peroneal nerve gives response also. No faradic response in any of the muscles of left leg. Thigh muscles and muscles of other limb respond to faradic current.

The question in the first case was whether there was really a recurrence of the infantile paralysis. If we rely upon hyperæsthesia alone it will sometimes mislead, and therefore Dr. Gibney believed that the only really reliable way to test the electrical reaction was to put the patient under the influence of an anæsthetic and proceed with exceeding care. It was a question, however, as to whether hyperæsthesia existed in the paralytic limbs during the first stage, or whether there was general myelitis at the time of the invasion sufficient to give rise to the various sensory disturbances. If it was allowed that hyperæsthesia did so occur, the view would be well maintained in the case presented if it was really one of polio-myelitis on the right side.

DR. PUTZEL remarked, concerning hyperæsthesia, that he had one hospital case under observation in which the disease began suddenly by severe pain in the upper part of the sacrum. On the next day severe pain extended along the course of the sciatic nerve, and continued three

days, and the patient also had a feeling as if pins and needles were in the right foot. At the end of that time the right limb was entirely paralyzed, and when he came under observation there was great atrophy of the whole limb, with absence of all electrical reaction except in the sartorius and one other muscle. The limb was also cold. Autopsy showed distinct polio-myelitis anterior in the right horn of the lumbar enlargement. He thought Dr. Gibney's case was especially interesting on account of the relapse. He had never seen an instance of this kind, and had not seen in literature any reference to its occurrence. He thought that the occurrence of the degeneration reaction would exclude the diagnosis of temporary paralysis merely, and make it really one of polio-myelitis.

The CHAIRMAN saw no reason why we should be dissuaded from the opinion that there was a recurrence of the disease simply because it was the inverse of what usually takes place. At the beginning of all cases of infantile paralysis we usually have a much greater area of manifestation than remains permanently paralyzed. That is, the child at the time of the invasion may have all the limbs paralyzed or paretic, and afterward the paralysis disappear entirely except from a single limb or portion of the limb. In Dr. Gibney's case there was the same order of events, and some time after distinct paralysis appeared, which did not spread; there was a later occurrence of paralysis affecting the opposite leg.

With regard to hyperæsthesia, any one who has examined many cases must have been struck with the fact that the typical outline given in the books does not correspond altogether with the facts as they exist in actual cases, for we find quite a number of children who bear the faradic current out of all proportion, which would imply a certain degree of anæsthesia. Of course, this might be explained to a certain extent by lack of sensibility in the nerves, but beyond that there is a certain degree of anæsthesia manifest to the faradic current. He had seen patients, adults, who had complained of numbness, tingling, a slight grade of anæsthesia, and after a time these cases had run a typical course of anterior polio-myelitis. It is sometimes very difficult to determine whether the case is one which will develop into the more marked diffuse myelitis or remain limited to myelitis of the anterior horn.

DR. GIBNEY asked the Chairman if degeneration reaction was apt to occur within the first week after the invasion.

The CHAIRMAN replied that it was occasionally seen at the end of six days.

DIFFERENTIAL DIAGNOSIS BETWEEN DELIRIUM AND INSANITY.

The CHAIRMAN reported certain cases which illustrated the difficulty and the importance of deciding whether a patient was suffering from delirium or insanity. He had seen a number of such cases in the last year. Of course, delirium, if continued and associated with hallucinations, constitutes one grade of insanity, but if it is possible to do so we should all prefer to call any given case one of delirium rather than one of insanity, both for the sake of the friends and for the sake of the patient. He had been struck by seeing cases which illustrated how closely these two conditions were allied, and how well some cases terminated in which there was delirium accompanied with delusions; for example, delirium in pneumonia, bronchitis, fever, or bronchial pneumonia, had continued for six weeks, and been the leading symptom.

(To be continued.)

THE MIDLAND MEDICAL MISCELLANY AND PROVINCIAL MEDICAL JOURNAL is an English monthly of a new and somewhat novel character. It aims to represent provincial medical work and seems very successful in doing so.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 26, 1883.

DAVID WEBSTER, M.D., PRESIDENT, IN THE CHAIR.

RESOLUTIONS ON THE DEATH OF DR. GEORGE M. BEARD.

DR. A. D. ROCKWELL offered the following resolutions:

Resolved, That in the death of Dr. George M. Beard this Society and the profession at large have lost one of their most brilliant, active, and earnest members. As an investigator he was original and conscientious. As a friend he was generous and steadfast. Exposed by his restless activity to many peculiar attacks, he ever manifested the utmost charity and good humor. Of his worst enemies, he seldom spoke a harsh, and never a vindictive word.

Resolved, That to his child, orphaned in one short week, by the added affliction of a mother's death, to his mother, brothers, and sister, we tender our heartfelt sympathy.

Resolved, That these resolutions be published in the medical journals of this city.

In presenting these resolutions, Mr. President, I would simply add, that having been associated for many years with Dr. Beard in a peculiarly close intimacy, it was my fortune to know him perhaps better than most others. His self-poise was remarkable. As a foil, so to speak, to the many attacks that followed his original investigations and his positive and independent methods of expression, he seemed almost to live and move and have his being in humor. His powers were of the most versatile character. His readiness and originality as a scientific writer are well known, but it is not so well understood that he had a genius for an entirely different sort of literary work. While a very young man, serving during the late war in the Gulf Squadron, and merely to give vent to his ever restless mind, he penned a work of fiction, which gave evidence of no mean talent in that direction, and since his death an autobiographical sketch has come to light, which, for its quaint humor, its keen estimate of character, and its philosophic insight is unsurpassed. I could say much in regard to this individuality, through which ran so rich a vein, and which in many respects was as unique and remarkable as any I have ever known or read of; but I forbear and content myself with the brief but just tribute embodied in the resolutions.

DR. D. B. ST. JOHN ROOSA—Mr. President: Before these resolutions are put I would like to say a few words in memory of my departed friend. It was my privilege to know Dr. Beard at the time when he and I entered the profession, and it continued to be my privilege to know him up to the time of his death. I think all of us must have been, during the last winter, particularly admonished of the frailty of the existence of even the strongest. When we recall the names of Draper, and White, and De Luna, and Beard, all men in the prime of life who have passed away, I think we must say that "the battle is not to the swift nor the victory to the strong." Dr. Beard possessed qualities which a physical infirmity did not allow of complete illustration. That physical infirmity in one instance at least had an untoward effect in prejudicing a large number of our transatlantic brethren against him. In an announcement that he made a certain experiment and laid his paper before the New York Academy of Medicine, a claim which he never made, he was not only misrepresented but was unable, in consequence of that physical infirmity, deafness, to appreciate the statement, and therefore did not have the opportunity to show that he had no intention of claiming any such thing. That statement was made one of the groundworks of a charge against him, and those of us who knew him best, whatever we may have thought of his scientific opinions, know that it was utterly mistaken. So in many other instances Dr. Beard was unable to enter fully into debates which his views originated, and therefore he was very much

handicapped. I simply allude to this in doing justice to his noble character, as we all know that in no instance had he ever departed from that which he believed to be entirely and completely true. He was a man, as has been said by the gentleman with whom he was so intimately associated for years, extremely tolerant of the opinions of others. He was a man who never retaliated upon those who seemed to make personal those matters which he regarded as merely differences of opinion on scientific or other subjects. He was a man far ahead of his age in many respects, and I believe that future generations will do more justice to some of Dr. Beard's statements than was done to them during his lifetime. I have more charity, perhaps, than some with reference to his opinions regarding the mental condition of the man who assassinated the President. I believe that his views regarding the mental power of man after the age of forty years will be more and more accepted, and also that his views concerning responsibility at certain periods in life will be more and more respected. I think his idea that the golden period in man's life, however much we may smile upon it now, is the middle period of life, will finally be accepted in all quarters of the world. I had the pleasure of being associated with him in making examinations with regard to the lesions which give rise to deaf mutism. This was early in his career, and these observations, and others I believe have taken a place in the literature of a certain department of medicine.

Dr. Roosa then spoke of his great work on electricity, written in association with Dr. Rockwell, a recognized standard text-book on that subject in all countries. He also referred to the remarkable fact that at one time Dr. Beard wished to read Tobold's writings in the original and to accomplish this he began the study of German, and so perfected his acquaintance with the language that in six weeks he was not only able to read the book but to present an acceptable translation to the medical profession. These were mentioned as illustrations of the versatility of his talent.

I am, Mr. President, in conclusion, very much reminded of the remark with which we are all familiar, made by Edmund Burke on the hustings at Bristol, deploring the loss of an antagonist who had been engaged in the same contest. "The worthy gentleman who has been snatched from us at the moment of the election and in the middle of the contest, while his desires were as warm and his hopes as eager as ours, has feelingly told us of the shadows we are and of the shadows we pursue."

I cannot accept the notion that we pursue shadows, fully as I admit that we are shadows ourselves passing along the galleries of time. I conceive with you, Mr. President, and others, that we are not pursuing shadows but realities in investigations for truth, and it is a hope we fondly cherish that Dr. Beard, to use the language of his own death-bed, "higher, higher," is pursuing the investigation, of what is never a shadow, truth in another sphere.

DR. W. M. CARPENTER—Mr. President: It was about the year 1873 that I made Dr. Beard's acquaintance, and that acquaintance, as it gradually increased, matured and ripened into a friendship which was both true and faithful. I had not heard of his sickness, and when the startling announcement of his death fell upon my ears I felt that I had lost a brother, and it is to the memory of that departed brother that I wish this evening to pay my humble tribute of respect. It has justly been said, Mr. President, that Dr. Beard possessed an active mind. Indeed, it may have been said of him that he was an enthusiast, if in the interpretation of that word we mean devoted, to the study of whatever subject he had under consideration. But I believe there was something more in his work than this. I think I can see, as I trace it from year to year, how he gradually stepped out of routine courses, and finally we find him engaging with those problems which gather along the border line between the seen and the unseen, between the knowable and the unknowa-

ble. It was in that field that his faculties found their greatest freedom. But in whatever department he worked, he wrought well, for he made a worthy fame, carved an enduring name and won a niche in the scientific temple of the last half of the nineteenth century. He indeed was enthusiastic, but he was not precipitate. He was bold in the expression of his opinions, but he was not bigoted. It has been said that he was erratic and visionary. The same, however, was said of men who lived before our generation, and who to-day are accredited with having possessed the brightest intellects of their times. In this great human caravan, keeping pace to the march of time, there are three classes of workers: first, and by far the largest in number, those who merely plod, and follow in routine courses or walk in circles; second, those who strive to make these routine courses and these circles easier and straighter by chipping off a little here and filling a little there, lessening the grade at this point and increasing the momentum at that; and, third, embracing only a very small fraction of this great multitude, those who are the advance workers, who do what is sometimes called "original work," who live beyond their time. It was in this field that Dr. Beard was laboring when the summons came. Therefore it was that any man who had the pleasure of his conversation could always carry away something that furnished food for thought. He worked because he loved to work; not as a slave, but as a child filled with and prompted by filial devotion, and in the very hour of his dissolution he expressed the hope that some one would take up his *work* at the point he left it and carry it forward, and he whispered the wish that he might be permitted, as a contribution to his *work*, to place upon record the thoughts of a dying man.

But his labor has ceased. In the prime of life, in the midst of greatest activity, in the mid-day of gathering usefulness his sun went down. But do we not see on the blue vault a golden radiance which marks the place where it sank beneath the horizon?

The resolutions were unanimously adopted.

The Society then adjourned.

INOSURIA.—Dr. Cochot concludes a thesis on this subject as follows: 1. Inosite (muscle sugar) is *never* met with in normal urine. 2. Urine containing inosite may also contain albumen or ordinary glucose. In some cases, however, the glucose disappears entirely, and is replaced for a time by inosite, or vice versa. 3. Thus inosuria is not a separate disease, but is a symptom which may be met with in Bright's disease or diabetes. 4. Whenever we find inosite in the urine we have to do with diabetes or albuminuria. The patient is exposed to the same dangers, and the effects of injuries are equally grave. 5. Since inosuria may supervene upon glycosuria it adds another difficulty to the diagnosis of the latter. For inosite does not turn the plane of polarization, neither does it give the characteristic chemical reactions of glucose. 6. Inosuria is to be suspected when the urine, boiled with Fehling's solution, throws down a flocculent precipitate of a greenish color. But certainty is only obtained by a thorough qualitative analysis. 7. It is of great importance to remember that a patient with inosuria is really the subject of Bright's disease or diabetes, in view of the gravity of operations or of wounds in general in such patients.—*Journal de Médecine de Paris*, January 13, 1883.

COFFEE IN TYPHOID FEVER.—The value of coffee as a heart and brain stimulant in adynamic conditions is perhaps not fully recognized. Recently Dr. Guillassee, of the French Navy, has given coffee in the early stages of typhoid fever with marked success. Three teaspoonfuls were given adults every two hours, alternating with one or two teaspoonfuls of claret or Burgundy wine. A beneficial result was immediately apparent.

Obituary.

WILLIAM HOLME VAN BUREN, M.D., LL.D.,
NEW YORK.

PROFESSOR WM. H. VAN BUREN, M.D., LL.D. (Yale), died in this city on the morning of March 25, 1883, within twelve days of the completion of his sixty-fourth year.

In his death a pillar of the profession has fallen, and a career has terminated the memory of which will long remain to serve as an example of honest dignity in professional life, an example which, in the commercial hurry of the present day, it would be well for the young physician to recognize and to emulate.

Born April 5, 1819, of a line of medical ancestors, in a family of refinement and education but devoid of wealth, Dr. Van Buren reached a position in the profession of the highest distinction, and dies reasonably mellow in years and ripe with honors.

His flexibility of person, his graciousness of manner, his dignified dexterity as an operator, his wide command of language as a lecturer, his elegance of diction as an author, the magic of his presence in the sick-room, will be long and pleasantly remembered by those who came into contact with him; while the keenness of his scorn and the pungency of his satire were only fully understood by those who ventured, in the heat of controversy, to impugn his motives or to attack the honest purity of his principles.

He entered Yale with the class of '38, but did not graduate; yet the college, in recognition of his literary attainments and distinguished position, decorated him with the honorary degree A.M. in 1866, and later, in 1878, conferred upon him the highest title in her gift, LL.D.

The University of Pennsylvania, in 1840, graduated him in medicine after his return from a tour in the Paris hospitals. He then served in the army until 1845, in which year he came to New York to assist the late Valentine Mott in the work of his clinique in the medical department of the University of New York.

During thirty-eight years he labored in the rich surgical fields furnished by this great metropolis, reaching early and distinguished honors which accumulated upon him as he advanced in life.

Among these may be mentioned the professorship of anatomy in the University, and of the science and art of surgery as well as of genito-urinary surgery and syphilis in the Bellevue Hospital Medical College. He did creditable work as an active surgeon to the Bellevue, the New York, and St. Vincent's Hospitals, and has been consulting surgeon to St. Vincent's, New York, Bellevue, Charity, the State Woman's, and the Presbyterian Hospitals. He was for many years active in medical society work, being vice-president of the New York Academy of Medicine and President of the Pathological Society. He figured also largely as a prominent name upon the consulting boards of many of the dispensaries and other medical institutions of the city. He was a corresponding member of the Society of Surgery of Paris, and his name was nearly as well known abroad as at home.

His first literary efforts were translations of French works, but soon able essays upon matters of personal experience appeared from his pen in the various medical magazines—essays marked by the honesty of the observations reported as well as their graceful elegance of expression. His "Contributions to Practical Surgery" appeared in 1865, his "Lectures on Diseases of the Rectum" in 1870, and again, in much better form, as a second edition in 1882. In 1874 he appeared as joint author with his junior partner in a text-book on "Genito-Urinary Surgery," and finally, his latest and perhaps ablest production on "Inflammation," came out in "Ashhurst's Encyclopædia of Surgery" only a short time before his death.

His work in the Sanitary Commission is a matter of

public as well as of medical interest. To the great detriment of his private revenue, he served his country faithfully upon this commission, and added largely to the efficiency of the medical and sanitary conduct of the war.

The credit of being the author of the tunnelling of urethral instruments attaches to his name. This improvement is perhaps second to none in modern urethral surgery.

He leaves a wife—a daughter of the late Valentine Mott—and two married daughters to deplore his loss.

His friends loved him devotedly, and he reciprocated their attachment with a fervor which could be counted upon in any emergency. When at the summit of his success, in the full rush of practice, he was particularly zealous in sustaining and assisting many younger members of the profession, most of whom hold his past favors in grateful remembrance.

His death was due, indirectly, to apoplexy, which occurred in the spring of 1882, directly, to degenerative changes about the injured cerebral focus, changes which set in with the beginning of the present year. He appreciated the approach of death, and wished for it. In communion with the mother church, and solaced by its sacraments, in the brightness of the Easter morning he ceased to be of earth.

New Instruments.

A COMBINED INSUFFLATOR AND VAPORIZER.

By C. J. CLEBORNE, M.D.,

MEDICAL INSPECTOR U. S. NAVY.

THE woodcut below represents an improved powder blower or insufflator, combined with a vaporizer for chloroform, rhigolene or other volatile substance.

A, insufflator; B, air-bulb; C, throat-tube; D, vaporizer; E, (elastic) uterine or urethral tube; F, ear tube (elastic).

The insufflator A is furnished with valves between A and B, in order to prevent fouling of the air-bulb B, which is to be used for both instruments. The insufflator (with or without the throat-tube C, or the uterine, urethral, or ear-tubes E and F) will be found useful in applying bismuth, calomel, iodoform, or other powder in the "dry treatment of mucous membranes." The vaporizer D is filled with sponge or cotton-wool, and is charged by dropping the chloroform or other volatile liquid upon the filling; then screwing the vaporizer (with its appropriate attachment) to the air-bulb B; by compressing the latter the vapor may be forced into any cavity of the body. In a form of neuralgic headache, described by the patient as "a pain far behind the eyes," or "on the floor of the brain," immediate and generally permanent relief may be obtained by inserting in the external ear its appropriate tube attached to the vaporizer, and then blowing with the mouth or air-bulb the vapor of chloroform into the ear. In a large number of cases of headache and earache of a neuralgic character, and in functional nervous deafness, relief has followed this procedure without any injurious result. The instrument is manufactured by Messrs. George Tiemann & Co., of New York.

A NOVEL TAPE-WORM TRAP.

TO THE EDITOR OF THE MEDICAL RECORD.

STR: While recently looking through the records of the United States Patent Office for another purpose, I came upon a most remarkable invention by Alpheus Myers, M.D., of Logansport, Ind. The invention, numbered 11,942, was patented November 14, 1854, and purports to be a *tape-worm trap*. It is described as follows:

"This trap is made of gold, and is shown set at Fig. 1, the length being less than an inch, and the diameter one-fourth of an inch. The separate parts, Fig. 2, are united by inserting spring *g* into cup *a*, and following the former by cup *d* and by cup *b*, which is held upon cup *a* by a bayonet fastening. In setting the trap stud *f* catches upon the top of cup *d*. Bait being placed in cup *b*, the trap is set and swallowed, after the patient has fasted several days, an end of cord *h* being returned from the mouth. The worm, in reaching the bait through opening *c*, pushes cup *d* from stud *f*, when spring *g* forces upward cup *d*, whose teeth seize the worm, when both the trap and worm may be withdrawn together. In this manner the inventor asserts that he has operated successfully.

Claim.—A trap for the removal of tape-worms from the stomach and intestines, constructed and operating substantially as herein described." C.

NEW YORK, March 3, 1883.

THE THIRTEENTH CRANIAL NERVE.—In 1881, Dr. Sapolini, of Milan, published a monograph bearing the above title. Dr. Burnett (*Medical Times*, February 24, 1883) gives the following résumé of the subject: Sapolini came to the conclusion that the so-called intermediary nerve of Wrisburg, lying between the seventh and eighth nerves at their origin, is the proximal portion of the chorda tympani, which really originates in the floor of the fourth ventricle and terminates in the lingual muscles. He followed this nerve up to the ganglion geniculatum in the facial canal; he then traced the chorda tympani backward to the same point and found that they were really one and the same nerve. To follow this down through the tympanic cavity and the canal of Huguier to its junction with the lingual branch of the fifth is an easy matter. His careful dissections show further that the two nerves now form a plexus in the muscles of the tongue, which he calls the plexus tympano-lingualis. He thinks that from its origin, both in the corpora restiformia and the lateral bodies, it must possess both sensory and motor fibres.

If now all this be true, this nerve must have special function, and to it Sapolini assigns that of governing speech. No articulate sound can be made without a motion of the tongue, and the slow progress in articulation made by children he explains by the late appearance of white matter in the floor of the fourth ventricle. Speech belongs to man, but with patience a parrot can be taught to speak. Two talking parrots, whose chorda tympani he cut suddenly, ceased to speak. To the chorda tympani alone then would he ascribe speech, while he holds that the lingualis of the fifth and the glosso-pharyngeal give the tongue touch and taste, and the hypo-glossal and lingualis of the seventh govern its movements in deglutition.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 17, 1883, to March 24, 1883.

MURRAY, ROBERT, Colonel and Assistant Surgeon-General. Detailed as member of Army Retiring Board to convene at the call of the President thereof, at Governor's Island, New York Harbor, for the examination of such officers as may be ordered before it. Par. 2, S. O. 62, A. G. O., March 16, 1883.

SUMMERS, JOHN E., Lieutenant-Colonel and Surgeon. Detailed as member of Army Retiring Board to convene at the call of the President thereof, at Omaha, Neb., for the examination of such officers as may be ordered before it. Par. 9, S. O. 62, A. G. O., March 16, 1883.

BILL, JOSEPH H., Major and Surgeon. Detailed as member of Army Retiring Board to convene at the call of the President thereof, at Omaha, Neb., for the examination of such officers as may be ordered before it. Par. 9, S. O. 62, A. G. O., March 16, 1883.

IRWIN, B. J. D., Major and Surgeon. Detailed as member of General Court Martial to meet at Whipple Barracks, Prescott, Arizona Territory, April 23, 1883, for trial of Captain J. P. Walker, 3d Cavalry. Par. 1, S. O. 62, A. G. O., March 16, 1883.

JANEWAY, JOHN H., Major and Surgeon. Detailed as member of Army Retiring Board, to convene at Governor's Island, New York Harbor, for the examination of such officers as may be ordered before it. Par. 2, S. O. 62, A. G. O., March 16, 1883.

BURTON, HENRY G., Captain and Assistant Surgeon. To be relieved from duty in the Department of the East, and will report in person to the commanding general Department of Dakota, for assignment to duty. Par. 1, S. O. 67, A. G. O., March 22, 1883.

GIRARD, JOSEPH B., Captain and Assistant Surgeon. Detailed as member of General Court Martial to meet at Whipple Barracks, Prescott, Arizona Territory, April 23, 1883, for trial of Captain J. P. Walker, 3d Cavalry. Par. 1, S. O. 62, A. G. O., March 16, 1883.

PORTER, JOSEPH Y., Captain and Assistant Surgeon. To be relieved from duty in the Department of the South, and will report in person to the commanding general Department of Texas, for assignment to duty. Par. 1, S. O. 67, A. G. O., March 22, 1883.

WINNE, CHARLES K., Captain and Assistant Surgeon. Granted leave of absence for three months from March 31, 1883, and will be relieved from duty in the Department of the East, and upon the expiration of his leave of absence will report in person to the commanding general Department of California, for assignment to duty. S. O. 61, A. G. O., March 15, 1883.

CAUTERIZATION OF THE CLITORIS IN THE TREATMENT OF HYSTERIA.—Dr. N. Friedreich (*Virchow's Archiv*, Vol. XC.) believes, with Baker Brown, that many cases of hysteria are caused by masturbation. Further, he is of opinion that in neuropathic females an over-sensitiveness of the sexual organs may exist, which acts upon the spinal and cerebral centres, causing hysterical symptoms, without there being actual, voluntary masturbation. He treats these cases by cauterizing the clitoris. The operation is most painful, but the results are so remarkable and agreeable that the patients, says Dr. F., never object to a repetition. Eight cases are reported, and all were ultimately cured. In two cases there were relapses, and the cauterization was repeated. In three other cases the cauterization had to be repeated. The disease was in all instances very marked, there being paralyses, general convulsions, hystero-epilepsy, etc.—*Journal of Nervous and Mental Disease*.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 24, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
March 17, 1883	0	13	111	4	96	50	2	0
March 24, 1883	0	10	113	6	102	52	4	0

A GRAVE-YARD INSURANCE COMPANY.—Dr. J. F. Jenkins, of Tecumseh, Mich., writes that his town has a Grave-Yard Insurance Company, composed of an undertaker as president, a homœopathic physician as secretary, and another of the same persuasion as examining physician. It is on the co-operation plan, and the chief feature of it is an "old people's" class, consisting of persons ranging from the age of sixty up to eighty-five years. They take policies on aged and infirm individuals, and sell these policies at the rate of five dollars apiece to any one whom their agents can find gullible enough to purchase them. The laws of the State of Michigan do not appear to reach this species of rascality.

BLUE-GUM STEAM IN THE TREATMENT OF DIPHTHERIA AND OTHER INFECTIOUS DISEASES.—Dr. G. Murray Gibbes, Taranaki, New Zealand, describes (*Lancet*) the result of his use of blue-gum (*eucalyptus globulus*) in the treatment of diphtheria. He takes the leaves and steams them, keeping the patient in an atmosphere of the steam. He has had thirty-seven cases in which this method was successfully used. Dr. Gibbes thinks it would be valuable in other infectious diseases, including phthisis.

SLAUGHTERING MERCIFULLY.—A well-known electrical engineer of London, Mr. George Lam Fox has devised an apparatus for the painless destruction of incurable and worn-out animals, especially horses. The animal to be killed, first has the top of its head and its feet and its legs wetted with salt water. It is then led into a stall and made to stand upon an iron plate connected with the negative pole of a condenser of a capacity of about one hundred microfarads. The operator then touches the animal's head with the positive pole, and it falls dead. The death is believed to be painless, because physiologists have demonstrated that a nervous vibration cannot be communicated to the brain in less than a tenth of a second, and another tenth of a second must elapse before a sensation can result from the vibration thus communicated. One-fifth of a second must, therefore, necessarily intervene between the actual infliction of an injury and the experience of pain from it. But the flash from such an apparatus, as has been described, presumably paralyzes every fragment of a nerve in man or beast in something like a hundred-thousandth part of a second. The difference between this swift and certain death and the horrible practice of the knacker's yard is sufficiently apparent to incline every humane person to fervently wish that this scientific mode of slaughtering may speedily be adopted. The idea, of course, is not new; but the application of the condenser to this business renders the process more certain and manageable than it was a few years ago. It is said for about two thousand five hundred dollars such an electrical apparatus as is here alluded to may be fitted up in any stable or outhouse, that it will kill as rapidly as animals can be placed in position and taken away again. We commend the matter to Mr. Bergh.

COMMENTS ON THE CODE.—Dr. Alexander J. Stone, Vice-President of the American Medical Association and late President of the Minnesota State Medical Society, said in his presidential address:

"The code, since its final adoption, has apparently been laid upon the shelf by the side of the family Bible, to be treated with almost as much reverence, to be read quite as seldom, and to be quoted only when its provisions enable one to discipline a rival, or to exclude him from the benefits of professional affiliation. A judicial consideration of the code forces a conclusion that much which it contains is gratuitous insult to the profession, and more, is rather calculated to amuse than to impress with respect the mind of the layman. There is not a clause or sentence in the first two articles which is not absolutely true; but, should the self-evident truths contained in Article I, be held constantly before the physician, as if by nature he was a brute who is to be taught the ordinary laws of humanity; a fool who must be taught a wisdom in the management of his patients which instinct alone would incultate; a knave who must be withheld from empiricism; or a man without the instincts of a gentleman? Granted that men enter the ranks of the profession to whom the epithets of 'fool,' 'knave,' or 'clown,' apply, of what value are the platitudes concerning brotherly love, or to what good is a formulated code defining the relations of medical men to the public or to each other? Among gentlemen such a code is unnecessary; among pirates it only serves to foster a cathauling hostility; as between a gentleman and a pirate, any difficulty which may arise is not to be satisfactorily settled by a reference to any code, because the standpoints from which each look at matters differ too widely—nor are the penalties which the code imposes such as to deter a real rascal, nor is that unsovereign body, the medical profession, able to enforce its laws rigorously."

THE INCREASE OF INSANITY IN NEW YORK.—The *American Journal of Insanity*, by a very elaborate and apparently careful analysis of statistics, tries to prove that the increase of acute insanity or of new cases in this State is not greater than the increase in the population. The total increase of insanity in 1882 was 633 cases, or 06.28 per cent. of all the insane in the State. The increase in acute cases, however, is estimated to be 01.4 per cent. while that of the population was 01.5 per cent. This estimate does not take into account the fact that many new cases are not put at once in asylums.

THE ST. MARY HOSPITAL of Brooklyn, of which one wing was recently completed, has been very severely criticised by the *Sanitarian* on account of its defective sanitary arrangements. We are told that it has cess-pool drainage, pan water-closets, and no ventilation worthy of the name. Our contemporary concludes: "No new demonstration is necessary to show the criminality of all hospitals constructed without regard to an abundant supply of pure air, and the danger of such plumbing as that which has been put into this institution. Unless these glaring defects are speedily remedied the structure is calculated to bring disgrace on the faculty and destroy all the promised utility of the institution."

MEDICAL CO-EDUCATION.—The Chicago Homœopathic Medical College has given up the plan of educating women. This is the second medical college which has abandoned medical co-education this winter.

THE CODE IN CANADA.—The *Canadian Practitioner* comments on the Code as follows: "In Toronto, we manage these things more quietly. One or two surgeons consult repeatedly with homœopaths, and, although they are members of both the Ontario and Canada Medical Associations yet, these societies meet in this city and—to their shame be it spoken—take no notice of the fact. We wonder if there be a latent fear that a discussion of the matter might reveal the existence of a general *advanced liberality* such as the State to the south of us has not blushed to proclaim."

A DENTAL COLLEGE AND INFIRMARY has been organized in Chicago under the auspices of Drs. N. S. Davis, William Byford, A. R. Jackson, and others. Rooms have been secured and the chairs filled. Students entering the infirmary must have matriculated in some medical colleges of good standing. After attending two courses of clinical instruction and found qualified, they will receive diplomas providing the degree of M.D. has been conferred.

Another new departure in medical teaching, says the *Chicago Medical Journal*, was inaugurated in the medical colleges last fall. Full chairs on dental pathology and surgery were added to several of the colleges, and instruction on dental and oral diseases was given in the regular winter course. These chairs were filled by graduates of medicine who are practising dentistry in Chicago.

ALMOST A SPECIFIC FOR SNAKE-BITES.—Professor Binz in seventeen cases found that filtered solutions of chloride of lime injected into the place where the virus entered, prevented any poisonous symptoms appearing. The suggestion is made that in cases of the bites from hydrophobic dogs, the same plan may be pursued.

PREVENTION OF BLINDNESS.—The fifth International Congress of Hygiene, which will meet at the Hague, Holland, in 1884, will award the prize of two thousand francs (\$400), offered by the London Society for the Prevention of Blindness, to the author of the best essay written in English, French, German, or Italian, on "The Causes of Blindness and the Practical Means for Preventing It." Besides this prize the International Society for the Improvement of the Condition of the Blind reserves to itself the right to award a second prize of one thousand francs (\$200), or two prizes of five hundred francs (\$100) each, and a silver gilt medal with a diploma, should it see fit, to such of the essays as should, in the opinion of the international jury for the principal prize, be deserving of it; the last-mentioned prizes will be distributed at the centenary festival of the first blind institution founded by Haüy, which will take place in Paris in 1884. The fourth International Congress of Hygiene, which met at Geneva, in September, 1882, adopted for this competition the following programme, as prepared by the London Society for the Prevention of Blindness: I. *The study of the causes of blindness*—*a.* Hereditary causes: Diseases of parents; consanguineous intermarriages. *b.* Infantile eye diseases: Various inflammations of the eyes. *c.* School period and time of apprenticeship: Progressive shortsightedness, etc. *d.* General diseases: Diatheses; various fevers; chronic poisoning, etc. *e.* Trade influences: Wounds and accidents, etc.; sympathetic ophthalmia. *f.* Social and climatic influences: Contagious ophthalmias; unhealthy habitations; defective lighting, etc. *g.* Neglect of treatment and bad treatment of eye affections. II. *The study of practical preventive means*—*a.* Legislative means. *b.* Hygienic and professional means. *c.* Educational means. *d.* Medical and philanthropic means.

The international jury elected by the Geneva Congress for the purpose of judging the essays, consists of—Holland: Dr. Snellen, Professor of Ophthalmology, Utrecht; Germany: Dr. Varrentrapp, Frankfurt; Dr. H. Cohn, Professor of Ophthalmology, Breslau; France: Dr. Fieuzal, Physician to the Hospice des Quinze-Vingts, Paris; Dr. Layet, Professor of Hygiene, Bordeaux; Italy: Dr. Reymond, Professor of Ophthalmology, Turin; Dr. Sormani, Professor of Hygiene, Pavia; England: Mr. Streatfield, Professor of Ophthalmology, University College, London; Dr. Roth, Honorary Secretary and Treasurer (*pro tem.*) of the Society for the Prevention of Blindness, London; Switzerland: Dr. Dufour, of the Ophthalmic Hospital, Lausanne; Dr. Appia, Geneva; Dr. Haltenhoff, Lecturer on Ophthalmology, Geneva, and secretary to the jury. Dr. Appia and Dr. Varrentrapp having resigned, the jury completed its number by elect-

ing Dr. Coursierant, oculist, Paris, and Dr. Berlin, Professor of Ophthalmology, Stuttgart.

Those essays to which prizes have been awarded will become the property of the Society for the Prevention of Blindness and of the International Society for the Amelioration of the Condition of the Blind, who will be at liberty to publish them, in whole or in part, in several languages, in order to make them useful in the way they consider best.

The inedited manuscripts for competition are to be sent to Dr. Haltenhoff, secretary to the jury, not later than March 31, 1884. Every manuscript has to be distinguished by a motto, which is also to be written on a sealed envelope containing the name, Christian name, titles, and address of the author. The envelopes will not be opened until after the award of the jury.

LUNACY IN SPAIN.—In 1879 the number of lunatic asylums in Spain was 26, with a population of 3,790, which gives a ratio of one to 2,250 of the whole population. About eight per cent. are discharged cured every year.

DARWIN'S RELIGION.—Karl Blind, in the Vienna *Neue Freie Presse*, notes the curious fact that the recent revelations regarding Darwin's religious opinions were only noticed by three or four of the English periodicals, and that even *Nature* suppressed Darwin's letter to a Jena student, which Haeckel had sent to the editor as part of one of his lectures. In this letter, it will be remembered, Darwin had stated verbatim: "For myself, I do not believe that there ever has been any revelation;" and in a conversation with Dr. Ludwig Büchner, he said he was with him in thought, but preferred the word agnostic to atheist, and that he had given up Christianity because "it is not supported by evidence." Karl Blind adds to this testimony another item, in the form of a letter written by Darwin in 1873, to a Dutch gentleman (N. D. Doedes) of which we give the following translation from the German, as given in the *Presse*: "I find it impossible to give a brief answer to your question. I do not know if I should be able to answer it if I should write a great deal about it. Thus much I can say, that the impossibility of understanding how this great and wonderful universe, besides our own consciousness, could have come into existence, through chance, seems to me to be our principal argument for the existence of a God; but whether this argument is of any value I have never been able to decide; for I know that, if we accept a highest cause, the mind again strives to know whence it came and how it arose. Moreover, I cannot pass over the difficulty which, on this assumption, arises from the vast amount of suffering prevalent in the world. I am, indeed, bid to attach a certain amount of weight to the judgment of the large number of intelligent men who have implicitly believed in God; but here, again, I see what an insufficient kind of proof this is. The safest conclusion seems to be that the whole subject lies beyond the range of human understanding; nevertheless, a man may do his duty."—*Gaillard's Weekly*.

THE INCREASE OF THE JEWS.—The *Lyon Medical* states that in general throughout Europe the increase among Catholics, Protestants, and Jews is as 1, 2, 3. In France and Austria the increase of the Jews is seven and four times that of the Catholic population. At the same time, the actual birth-rate of the Jews is as a rule lower than that of Catholics and Protestants; but illegitimate births are very rare among Jews, and the infant mortality is very much less. In general, among the Christian population, the number of girls and boys is nearly equal, the boys being slightly more numerous, the figures being 105 to 100; but among the Jews of Russia, Prussia, Austria, Hungary, and Verona, the proportion rises from 110 to 120 and 130 boys for 100 girls. This predominance is believed by Dr. Lagneau to be the consequence of the early marriages of the Jews.

ON VARIOLA.

ITS DEFINITION, HISTORY, CAUSE, VARIETIES, PROGNOSIS, AND TREATMENT.

By J. N. MCCHESNEY, M.D.,

LATE ONE OF THE ATTENDING PHYSICIANS TO THE HOSPITAL FOR CONTAGIOUS DISEASES OF THE CITY OF NEW YORK.

(Continued from page 342.)

Variole Anomale.—Small-pox occurring with other diseases, or presenting unusual features, is called anomalous. We have seen scarlatina, diphtheria, and variola in the same person. The patient, while sick with a mild attack of discrete small-pox, slept in a bed which had been occupied by a scarlatina patient. The scarlatinal eruption developed regularly, and all of the symptoms were very severe. The diphtheritic deposit was abundant. Desquamation in both diseases took place at the same time, and the patient made a good recovery. In another case variola developed in a female patient who was desquamating from scarlatina. The attack was mild, and she recovered after a slow convalescence.

A rare complication occurred in a case of variola at the Riverside Hospital in the spring of 1881. A patient was admitted with discrete small-pox, and in a few days desiccation began. About this time the temperature went up to 104° or 105°, the patient became delirious, and in a few days a petechial eruption made its appearance on the trunk and upper extremities. The symptoms and eruption were those of typhus fever. The man was a tramp, admitted from one of the lodging-houses of the city which were making daily contributions to the typhus wards of the hospital, and the chances of exposure were many. Later in the case, cerebro-spinal meningitis was developed and the case terminated in death. An autopsy confirmed the correctness of the diagnosis.

Pregnancy is a complication which is of serious consequence; abortion generally follows with fatal results to both mother and child.

Another anomalous condition is the birth of a child with the eruption on its body. It is obvious in this case that the disease must have been conveyed to the foetus and the stages of incubation, invasion, and partly of eruption passed in utero.

We have met with a number of cases of variola complicated by pregnancy. In most of them abortion occurred, though in one or two recovery took place and the child was born at full term. In only one instance have we seen the foetus born with the eruption. The history of the case is as follows:

Mrs. F—, aged thirty; native of this city; vaccinated in childhood; fair cicatrix. First seen on February 11, 1882, and found to be sick with discrete variola in the vesicular stage. The initial stage had been moderately severe; the eruption was abundant on the face and extremities, scant on the trunk. At this time she was about two and a half months pregnant. The disease ran a modified course, and on March 11th, a little more than one month after the beginning of the attack, quarantine was raised and she soon resumed her household duties. Quickening occurred in the first week of April. On the 23d of that month she ceased to feel any fetal movements, and three weeks passed without any signs

of life in the foetus; two careful examinations, made at different times, failed to discover any evidence of life, which, taken with the fact that the abdominal tumor had diminished in size, rendered it quite probable that death had occurred. On June 6th she was delivered of a dead female child. There was little or no decomposition. Forty or more distinct pustules were counted on the body. They were most abundant and better developed on the trunk and about the folds of the axillæ and groin, where they were grouped in twos and threes; they were also present in the palms of the hands and soles of the feet. The pocks varied in size from the head of a pin to a pea, the largest being on the posterior aspect of the trunk. There was no evidence of umbilication.

Many questions of interest are present in this case, the discussion of which would, however, exceed the limits of this paper.

Several cases of small-pox in females recently delivered were admitted to the hospital. The eruption made its appearance on the children when they were only a few days old, showing that the contagion had been conveyed to them, and nearly the whole period of incubation passed, in utero. In several of the pregnant cases the children were born at full term, apparently strong and vigorous, without any evidence of having suffered from the disease before birth. These children were vaccinated at the age of three months. In one case three attempts were made before vaccination was successful.

One case, seven months pregnant, had discrete hemorrhagic variola, with a moderately abundant eruption. Abortion was threatened, but the course of the disease was modified. She passed safely through the attack and was delivered of a living child with no traces of the disease on its body. It was puny and delicate, however, and died of infantile diarrhœa a short time afterward.

Variola sine exanthemata, or small-pox without the eruption, is an anomalous form which now and then occurs during the prevalence of an epidemic. Early in 1881, while attending the wards of the small-pox hospital, at a time when there was a number of unusually malignant cases, the writer was seized with rigors, headache, obstinate nausea and vomiting, intense pain in the lumbar region, rapid pulse, temperature went up to 106° F.; the tongue was heavily coated with thick yellowish white fur, and complete anorexia existed. The fauces were inflamed and swollen. The temperature remained high, in spite of heroic doses of quinine and cold sponging, until the fourth day, when it fell to the normal and all other symptoms disappeared. Careful examination was made, but not the slightest trace of eruption could be discovered. Vaccination had been successfully performed only a month or two previous and doubtless prevented the appearance of the eruption. The following case, related by a writer on this subject, is interesting as illustrating this form of the disease as well as the occurrence of variola in the foetus:

"During a severe epidemic of small-pox, a midwife, forty years of age, in the eighth month of pregnancy, fell sick with rigors, followed by violent fever, headache, pain in the back, etc., apparently the initial stage of small-pox. On the fourth day, however, she was free from fever, and in spite of the most careful examination, exhibited no trace of the expected eruption. Ten days after the commencement of the disease, feeling perfectly well, she gave birth to a child covered with a small-pox eruption, evidently just appearing, which developed still

further, and in three days terminated in death during the stage of supuration."¹

A variety of anomalous small-pox called *variola verrucosa* (from *verruca*, a wart), in which the disease assumes a mild form, is occasionally seen. The initial stage may be as severe as in the worst types of the disease, but the severe symptoms subside early in the eruption, which assumes a modified form. Some of the pustules shrivel up, while others mature; desiccation is early; there is no secondary fever; the scabs fall off and leave little or no pitting.

Complications.—The complications and sequelæ occurring with, and subsequent to, small-pox are numerous and varied, often leading to a fatal termination when the disease itself is not necessarily so. The number and variety of complications and sequelæ differ very much in different epidemics, and at different times of the same epidemic. Erysipelas, abscesses, etc., abound in some epidemics and are comparatively rare in others. Among the patients admitted to the hospital in 1881 the complications were numerous—erysipelas, crops of boils, large, diffuse abscesses, two or three cases of gangrene, ulcerations of the cornea, with destruction of one and, in one instance, of both eyes, several cases of pyæmia, and nearly every other complication. The frequency of erysipelas may be accounted for by the fact that during the winter of 1880, and the spring following, that disease prevailed to an unusual extent in this city.

During the stage of secondary fever, in the more severe forms of the disease, when desiccation is taking place, crops of boils appear, diffuse abscesses occur in different parts of the body, the pus burrows underneath the skin and between the muscles, forming sinuses and not unfrequently causing extensive destruction of tissue. These are apt to occur in the neighborhood of old wounds and recent bruises. Glandular swellings occur now and then, and frequently result in supuration.

Large bed-sores are formed on those parts where there is any pressure. In one case, that of a negro man, the whole sacrum was uncovered and both trochanters were exposed; he recovered from his attack of small-pox, but succumbed to the exhaustion consequent upon this ulceration. The hair falls out in some cases, leaving the patient completely bald. Fortunately, however, unless there has been great ulceration, or erysipelas of the scalp, it is generally reproduced. The nails fall off occasionally. We have met with one case of well-marked pyæmia in a boy who had a semiconfluent eruption. There were frequent rigors, high temperature, nausea, numerous small boils and ulcerations, with collections of pus in all of the large joints. Death occurred in a few days.

Gangrene, fortunately, is of rare occurrence. We have seen three cases: one of the right forearm, in a man with confluent hemorrhagic small-pox, and the other two of the scrotum. One of the latter had discrete variola, which was complicated with gonorrhœa. Nearly the whole of the scrotum sloughed away, leaving the testicles bare. The ragged edges were trimmed, the testicles pushed up into the abdominal rings, and aided by the elasticity of the tissues the edges were easily approximated and united in a central raphé. Union was speedy and complete, giving him a short but useful scrotum. He will probably never suffer from varicocele, or be under the necessity of wearing a suspensory bandage.

Of the internal organs the pleura is the most disposed to take on inflammatory action. Pleuritis is one of the most painful and fatal complications; it supervenes suddenly, and runs a rapid course. One of the cases which occurred in the hospital was in an adult negress. The attack was not of a very acute nature; the effusion in the right chest was very large—became purulent, perforated an intercostal space, and formed a large abscess in the axillary region; this was opened and fully three pints of offensive purulent fluid withdrawn. The case

terminated in death, and autopsy showed the whole right chest filled with fluid of the same kind; the pleura of the left side was also involved.

Pneumonia of the congestive variety frequently occurs. Inflammation of and purulent discharges from the ear are of occasional occurrence. Conjunctivitis, of more or less severity, is a frequent complication; it is due to the presence of the pustules on the margins of the eyelids, and on the palpebral and sclerotic conjunctivæ.

A complication of tolerable frequency, which generally results in serious mischief to the patient, is ulceration and perforation of the cornea. We have seen several patients lose one eye, and one case became completely blind from this cause. The trouble first shows itself as a small whitish speck at the margin of the cornea, generally on the inner side. It may disappear, or give rise to an opacity of such size as to interfere with vision, or else destructive ulceration may ensue, resulting in perforation of the cornea, escape of the aqueous, and loss of sight. In one case of perforating ulceration we had the startling accident occur of having the lens pop out into our hand while attempting to separate the lids to examine the progress of the ulceration.

The nervous system is now and then implicated. Two brothers, Canadians, were admitted to the hospital about the same time; in the suppurative stage both had hemiplegia, and one, the elder, aphasia; both died. In two cases we have seen insanity; one patient made a complete recovery, the other committed suicide after recovering from small-pox.

A sequel which occurred in five cases, all of them except one being negroes, was œdema of the left foot and ankle. The swelling extended from the instep to several inches above the ankle, was painless and unattended by heat; the urine was examined for albumen and casts, but the result was negative. The cause of the swelling was doubtless due to some obstruction of the venous circulation. It passed away without any further trouble.

As a rule, one attack of small-pox renders the person insusceptible to the disease for the remainder of his life. Exceptions do occur, but are of less frequency than the statements of patients might lead one to suppose. We have seen but two cases of recurrent small-pox; the first was in a young man aged twenty-two, who was admitted with a discrete form of the disease, which ran its course in about two weeks. On the night previous to the day on which he was to have been discharged from the hospital, he was seized with rigors, headache, pain in the back, and the other initial symptoms of variola, which so closely resembled the symptoms that ushered in his first attack that he remarked, "I believe I am going to have a second attack of the disease." The eruption appeared on the third day, and ran a course similar in every respect to the first attack. The second case was that of an Italian child, not vaccinated; the variety was discrete from which it recovered and was discharged from the hospital. In less than a month it was again sent to the hospital with the disease, which proved to be of the confluent variety, and ended in death.

Several patients were admitted who exhibited the pits of a former attack. Two or three who had mild discrete small-pox claimed and exhibited cicatrices resulting from inoculation, done years before in the "old country."

Diagnosis.—It is always of the greatest importance to decide upon the nature of febrile eruptive diseases at the very earliest moment, in order that isolation of the patient and other precautionary measures may be taken for the protection of those who may have been exposed.

While we recognize the importance of early diagnosis, we should be exceedingly careful not to declare an eruptive trouble only measles and harmless, or, on the other hand, to decide it to be small-pox, and have the patient removed to a small-pox hospital, where, if he has not the disease, his chances for contracting it are greatly increased, before the evidence in the case warrants our giving a decided opinion. When small-pox is

¹ Churschmann in Ziemssen's Encyclopædia.

prevalent, mistakes in diagnosis frequently occur, growing out of undue haste and want of careful examination of the patient. In every case where doubt exists the patient should be isolated and closely watched.

In natural or unmodified variola, after the eruption is well out, there is little or no difficulty in making a diagnosis. No one symptom, or series of symptoms, before the appearance of the eruption, is sufficient to justify a positive opinion. All of the symptoms, taken in conjunction with the character of the eruption, should be carefully considered before deciding whether we have small-pox, or one of the less dangerous eruptive fevers, to deal with. It will be of great assistance to find out whether there has been any exposure to small-pox, also whether the patient has been recently vaccinated or re-vaccinated. In regard to vaccination, the statements of the patient or of his friends is not alone to be relied upon, but the arm should invariably be examined for a vaccine cicatrix.

The diseases which in the early stages are most apt to occasion difficulty in diagnosis are measles, varicella, scarlatina, febrile lichen, and some of the skin diseases. Many of the symptoms of the initial stage of variola—as chills, fever, headache, aching of the limbs, nausea with vomiting, and anorexia, are common to the other eruptive fevers, but the intense lumbar pain which accompanies these symptoms in small-pox is rarely found in the other diseases. In some cases of small-pox the pain in the back is not so pronounced, and its absence does not exclude the possibility of that disease.

The duration of the initial stage is a point for consideration; in small-pox it is from two to four days; in measles, four to five; in scarlatina, one day; in febrile lichen the eruption appears on the second day; varicella can scarcely be said to have any prodroma.

The presence of catarrhal symptoms—redness of the conjunctivæ, burning, smarting pain in the eyes, sneezing and coughing, and known exposure are in favor of measles; the temperature of the initial stage of measles is not so high as in variola—is seldom above 102° to 104° F.

The early appearance of throat symptoms, the strawberry tongue, and a diffuse eruption showing itself on the second day, favors scarlatina.

In the initial stage, the symptoms of greatest diagnostic significance in favor of small-pox are obstinate nausea and vomiting, the intense pain in the lumbar and sacral regions, and a temperature of 104° to 106° F. These, with the other symptoms and a known exposure to contagion, should put us on our guard. A positive opinion, however, is not to be given until the characteristic eruption is established.

The eruption of variola appears on the third day, consists of small red spots or macules, seen first about the mouth, nose, and chin, and at the same time on the fronts of the wrists and forearms. In twelve to twenty-four hours papules are formed; these change to vesicles, in which the central depression or umbilication is seen.

In measles the eruption is first seen on the forehead and about the temples, extends rapidly over the face, neck, and trunk, but more slowly over the lower extremities. The confounding of small-pox with measles usually occurs in the papular stage of the eruption; the papules of variola are smaller and have a hard, shot-like feel; those of measles are larger and softer.

Vesicles are to be carefully sought for, and if found with umbilication, decide the question. They are often found first about the axillary folds, inner face of the arms and thighs, where the skin is thinnest. The mouth and throat should be examined for the eruption. In measles it appears as a mottled redness; in variola the spots are round, whitish or ashy.

The eruption of scarlatina appears on the second day about the neck and chest, is diffuse, and extends rapidly over the whole body. The general erythematous con-

dition of the skin accompanied by redness of the fauces, which sometimes precedes the eruption of variola, may lead to the diagnosis of scarlatina. We have known this to occur in one or two instances. This erythematous redness is of a brighter scarlet tint than the eruption of scarlatina, which is more dusky in hue; it is not so generally diffused over the whole surface; the faucial symptoms are more pronounced in scarlatina. Crops of miliary vesicles are now and then met with in scarlatina, and may give rise to doubts. These occur chiefly about the sides of the neck and upper part of the chest, are small in size, do not umbilicate, dry up in a day or two and desquamate.

The eruption of febrile lichen appears on the second day as small papules on the trunk and face at the same time, and does not vesiculate. The duration and character of the prodromata and the difference in the eruption, will decide between this affection and variola.

The fall of temperature and disappearance of the symptoms of the initial stage after the eruption is established, is a strong diagnostic point in favor of small-pox. It does not occur in any of the other eruptive fevers.

The diagnosis of modified small-pox or varioloid from varicella is not always an easy matter, and the more modified the small-pox, the greater the difficulty. They are frequently confounded, and such errors have led to incalculable mischief. To mistake varicella for varioloid and send the patient to a small-pox hospital, where in all probability he would contract small-pox, would be a great injury to him; but to mistake a mild case of variola (varioloid) for varicella, would lead to far more serious consequences, from the lack of the necessary precautions to prevent the spread of the disease. We recall a case which occurred in the person of an only son, in a family, living in this city, which illustrates the serious consequences of the latter error. After a mild stage of invasion an eruption made its appearance. There was a difference of opinion among the physicians who saw him as to the nature of the disease; the diagnosis of varicella prevailed, and the case was treated accordingly. The patient only remained away from business for a day or two. It was deemed advisable to vaccinate the members of the family, and this was done except in the case of the mother, who was excepted because she had had an attack of small-pox when young. In due time she was attacked with confluent hemorrhagic variola, of which she died.

Varicella usually, though not invariably, occurs in children. There is scarcely any appreciable systemic disturbance, though exceptionally there may be a mild stage of invasion, lasting twenty-four hours. The eruption is vesicular almost from the beginning, appears first on the body as small spots which can be felt, but there is no hardness as in small-pox. The vesicles are present on the face and scalp, but are most abundant on the trunk, and are largest about the shoulders and between the shoulder-blades. They may attain the size of a split pea, though frequently are no larger than the head of a pin. They are very superficial, and look as if caused by a shower of boiling water. The contents of the vesicles become turbid, but not purulent, unless they are irritated. As a rule the vesicles are not found in the palms and soles, and, when found there, are along the radial and ulnar borders of the hand, and the inner and outer sides of the foot—not in the centre. Umbilication is now and then observed, but is not so universal as in varioloid. It may be due to the presence of a hair-follicle, or the depression resulting from the escape of a portion of the contents of the vesicle. However this may be, its presence may lead to error, and alone it should not be taken as a decided point in favor of varioloid. The vesicles of varicella are less often found on the mucous membranes than in varioloid.

The presence of a characteristic cicatrix, due to a recent vaccination, is strongly, if not positively, against varioloid. Supposed varicella, occurring in adults, is

always suspicious and should be very carefully looked into. In many cases it will prove to be varioloid.

Some dermatologists, among them Hebra, consider varicella and varioloid to be identical, but a careful comparison of the two diseases will demonstrate the error of these views. The following history of a series of cases that occurred in the experience of the writer will serve to controvert the above opinion :

CASE I.—Maud H—, five and one-half years of age ; vaccinated when four years old, good cicatrix. On January 8th, after little or no general disturbance, a vesicular eruption made its appearance, most abundant on the trunk, and ran its whole course in about one week. Diagnosis varicella.

CASE II.—Margaret H—, two years of age, sister of Maud : vaccinated when nine months old, excellent cicatrix ; was taken sick (January 21st) one week after the recovery of her sister ; after a slight indisposition, had an eruption identical in every particular with that in her sister's case.

CASE III.—Jennie W—, eight years of age ; never vaccinated ; lived on the first floor of the same house and was a playmate of the H—s. Was sick first on February 5th : her symptoms, the appearance and duration of the eruption, were the same as in the other cases.

In February an uncle of the H—s came to visit them. On the 15th was sick with the following history :

H—, twenty years of age : exhibited cicatrix of a vaccination done in infancy ; began to be sick on the afternoon of February 15th, with chills, headache, pain in the back, fever, anorexia, etc. On the 17th "pimples" were noticed on his face and wrists, which changed to vesicles, and later some of them became pustular ; the eruption was present in the palms of the hands. The initiatory symptoms abated as soon as the eruption appeared and the patient was not confined to his room after the 27th, though the spots of the eruption and pigmentation were plainly seen after convalescence. The occurrence of this case, after the illness of the children from varicella, and the similarity of the attack, led to the conclusion that this case also was one of varicella, "only a little more severe," and no physician was called.

On February 27th, J. H—, a brother of the young man, began to be sick and had all the symptoms of the initial stage of variola. No eruption appeared, but on the fourth day the fever subsided and all of the symptoms disappeared. This was in all probability variola sine variolis.

On March 2d, H. W—, forty-six years of age, father of Jennie W—, had the first symptoms of small-pox. The eruption appeared on the 5th. He was removed to the hospital ; the disease assumed the confluent form, and death ensued on March 14th.

Jennie W—, eight years of age, never vaccinated, recently recovered from varicella, taken sick with the first symptoms of variola on March 4th ; the eruption appeared on the 7th. She was removed to hospital with her father. The form was discrete small-pox. She recovered and was discharged from hospital on the 24th of the month.

These cases illustrate not only the many points of diagnostic difference between varicella and varioloid, but also the fatal consequences of mistaking one for the other ; and further, that an attack of varicella does not prevent the occurrence of variola, since Jennie W— had scarcely recovered from the former when she was attacked by the latter. All of the cases of varicella were in children—two vaccinated and one unvaccinated—which illustrates the fact that vaccination does not act as a preventive against varicella. The supposed case of varicella in the adult was undoubtedly modified small-pox (varioloid), he having been vaccinated in infancy, as the occurrence of the three cases of variola in the same house are clearly traceable to him. The benefit of vaccination is illustrated by the fact that the two nieces of H—, both having the protection of comparatively re-

cent vaccination, escaped, notwithstanding constant exposure in the same rooms. Jennie W—, though not so constantly exposed, being unprotected by vaccination, contracted small-pox.

Of the diseases of the skin, those most likely to be mistaken for small-pox are pustular acne, papular eczema, ecthyma, and some forms of the secondary syphilitic eruptions. By strict attention to the stage of invasion, careful observation of the characteristic points of the eruption, and noting the regular development of, and the changes in the form of the eruption of variola, there will be little difficulty in making the distinction.

The question of diagnosis between typhus fever and the petechial type of hemorrhagic variola occasionally presents itself. Reliance is to be placed in the differences in the symptoms and duration of the initial stage, and upon close observation of the appearance of the eruption and the changes which occur in variola. Vesicles should be carefully sought for, and if present will decide the point. The temperature of variola abates on the development of the eruption, in typhus it does not.

Purpura hæmorrhagica has been mistaken for petechial small-pox, and, during the prevalence of variola, deaths are now and then reported as caused by the former, when investigation proves them to be due to the latter.

Hemorrhagic spots are occasionally seen in acute rheumatism, which may lead to a diagnosis of petechial variola. The writer has met with one such case.

Sudamina, and miliaria occurring in fevers and diseases in which there is profuse acrid perspiration, notably rheumatism and scarlatina, have been diagnosed variola. With a little care this need not occur. The vesicles are consequent upon profuse acrid perspiration, are minute in size, contents very clear, generally found at the root of the neck, around the shoulders and sides of the thorax ; there is no redness at their base ; they attain full development in a few hours, remain so for about a day, and either burst or dry up. We have met with one case in which a profuse crop of sudaminous vesicles appearing in a patient subject to rheumatism led to the diagnosis of variola. In this instance they were even noticed beneath the hardened cuticle of the palms.

Now and then cases are encountered in which the eruption of small-pox is found coexisting with the eruption of syphilis, and the detection of variola on first examination is extremely difficult. The symptoms and appearance of the eruption must be carefully considered ; an attempt to make a diagnosis on the appearance of the eruption alone may lead to discomfiture. We have seen one case of this kind, occurring in a Cuban negro. The presence of a pustular syphilide was recognized, but a few days of fever, with the other symptoms of the initial stage of variola, with new points of eruption appearing, and small-pox being prevalent, gave good grounds for the suspicion of the coexistence of the two diseases. He was isolated, and, after a few days watching, variola was excluded.

Prognosis.—In predicting what will be the probable termination in any particular case of small-pox, we should be guided by the following points : the character and quantity of the eruption ; the age of the patient ; the extent of the implication of the mucous membrane of the larynx and trachea ; the previous habits and condition of the patient ; whether vaccinated, and if so, how recently ; the complications, their nature, etc.

Discrete variola when uncomplicated is attended with but little danger. Of 657 cases admitted to the Riverside Hospital for 1882, 409 were of this variety, and but 25 of these died—a mortality of 6.11 per cent. The danger to life is not from the disease *per se*, but if death occur it is usually from some complication. A semiconfluent eruption greatly increases the danger to life.

The prognosis of confluent small-pox should always be guarded, and cannot be given with safety in the early stages of the disease. Confluency about the face is unfavorable, as these patients frequently die, although the

eruption may be discrete on the other parts of the body. When the pustules do not fill out, but remain flat, and the eruption has a dirty whitish, pasty appearance, recovery almost never takes place. A deep, clarety-colored areolæ surrounding the pustules, is to be regarded as unfavorable. In the year 1882, of the 657 cases of small-pox admitted to the hospital, thirty-one were of the confluent variety, of which number only four recovered.

Recovery from the petechial type of hemorrhagic small-pox is so rare that it may be said never to occur. Death very frequently occurs from the intensity of the poison before the eruption is established. From confluent-hemorrhagic small-pox recovery rarely, if ever, takes place. There were thirty-seven cases of this form in the hospital in 1882, all of which died.

Age occupies an important place in prognosis, the mortality being greatest among young children and the aged. The least mortality takes place from ten to twenty years of age.

TABLE II.

Showing the Total Number of Cases admitted to the Riverside Hospital, for the Years 1880, 1881, 1882, arranged according to Ages, with the Ratio of Mortality for each Period.

	AGES.										Total
	0-5	5-10	10-20	20-30	30-40	40-50	50-60	60-70	70-80		
Admissions	456	159	281	637	311	112	46	9	3		2,014
Deaths	247	37	53	135	68	32	16	4	3		595
Mortality per cent. .	54	16	23.27	18.86	21.19	21.86	28	57	34	78	29.54

Although the mortality is greater among young unvaccinated children, it is to be remembered that mild, discrete small-pox does occasionally occur and recovery take place.

In the year 1881, of 1,259 cases of small-pox admitted to the hospital, 138 were in unvaccinated children of two years and under. Recovery took place in 41 of these.

The patient's having been vaccinated will make an important difference in prognosis. The recency and thoroughness of the operation is of more importance than any number of cicatrices resulting from the same operation.

The stage of invasion of small-pox in those who have been vaccinated may be of the severest nature, yet the eruption is usually discrete and runs a modified course unattended by any great danger.

The symptoms which justify a grave or unfavorable prognosis are : great prostration ; rapid and feeble pulse ; low muttering delirium, or intense restlessness ; diarrhœa ; general confluence of the eruption ; the formation of large blebs or bullæ ; a flat, white, pasty appearance of the eruption ; the appearance of a dark spot in the centre of the pustule during maturation ; a livid, purple color of the vesicles and surrounding surface ; hemorrhages into the vesicles and from the mucous surfaces ; abundance of the eruption in the throat and larynx.

Pregnancy is a most dangerous complication and renders prognosis unfavorable.

During the stage of desquamation the occurrence of pleurisy, pneumonia, erysipelas, gangrene, numerous abscesses and sinuses, and prolonged exhaustive suppuration render the prognosis unfavorable.

(To be continued.)

INTERESTING SANITARY EXPERIMENT.—An interesting debate took place in the Italian Parliament recently on the employment of convicts in agricultural operations, which has been going on for some years at the Abbey of the Tre Fontane in the Roman Campagna, under the direction of the Trappists. The object with which these works were started was to ascertain if the cultivation of the soil would result in purifying the air of the Campagna, the general opinion being that the malaria is caused by atmospheric influences unsuceptible of modification. The results so far have been most satisfactory. At first the monks were obliged to live within the city walls during the bad season, but since the ground has come under cultivation, and, above all, since the Eucalyptus globulus has been planted on a large scale in the neighborhood, the Abbey has been inhabited all the year round, and the fevers from which its inmates still sometimes suffer are of a mild character, and rarely fatal ; whereas at the outset something like a fourth of the little community succumbed every year. The debate proved that the health of the two hundred and eighty convicts employed on the works was satisfactory, the average annual deaths from malaria not exceeding three. The government has lately made a very large grant of land in perpetuity to the Trappists, who have already planted on it no fewer than one hundred thousand eucalyptus trees, which are all doing well.

ON THE
PRODUCTION OF IMMUNITY FROM CONTAGIOUS
FEVERS BY INOCULATION WITH
DILUTED VIRUS.

By D. E. SALMON, D.V.M.,

ASHEVILLE, N. C.

A FEW years ago, a considerable number of extremely ingenious and instructive experiments were made by M. Chauveau, which demonstrated beyond the possibility of doubt that the active principle of virulent liquids consisted of solid particles held in suspension and not of soluble chemical substances. These experiments were modelled after those of Spallanzani with the spermatic fluid, by which he proved so conclusively that the fecundating agent was not the *aura seminis* of the older philosophers, but existed as suspended and insoluble particles.

The idea of one series of experiments was to obtain the results of inoculations with diluted virus. If, after the dilution was carried to a certain extent, the inoculations in some cases produced the disease and in others did not affect the animals, he reasoned that this must be due to the fact of the solid particles being too few to exist in every drop of the diluted liquids, and that the disease was only caused by those drops which contained one or more of the virulent particles. If the virus was a soluble poison, it should exist equally in every drop, even of the greatest dilutions.

Practically he found that virus diluted to the same degree sometimes produced the symptoms of the malady with all their intensity, while sometimes it had no effect whatever. Vaccine virus diluted to one-fiftieth nearly always failed, and this was accepted as a proof of the theory that the active agent consisted of solid particles too few to be inserted in every inoculation puncture. Similar experiments were made by way of confirmation with the virus of small-pox, sheep-pox, and glanders.

From that time until the present, no one, as I am aware, with the single exception of Chauveau himself, has ever expressed a doubt in regard to the ability of a single disease-germ, once introduced into the tissue of the body, to produce the disease with all its characters. On the other hand, our best scientific authorities have felt confident in assuming that because disease-germs evidently have the power of multiplying themselves indefinitely, when the conditions are favorable, a single one of these would produce the disease as certainly as a larger number, though it would probably require a longer period of incubation.

Strange and inexplicable as it may appear to us, this assumption is not in accordance with the truth, and if the conclusions from all of M. Chauveau's experiments had been as defective as with this series, which happily they were not, we might well have doubted the power of man to solve a problem so complicated and mysterious.

If we examine a drop of fresh vaccine lymph, with suitable precautions, we will have no difficulty in deciding that it contains many more than fifty germs, and that, consequently, if Chauveau's reasoning was correct there should have been no failures with dilutions of one to fifty.¹ Again, Chauveau's experiments with diluted virus, like those of every other investigator who has attempted the same line of research, are unreliable and defective, because, first, lymph, blood, or other liquids taken from the animal body contain cells, organic *débris* and coagula to which the germs adhere and which prevent their regular diffusion in the diluting liquid; secondly, because the number of germs in a drop of lymph from different pustules, or in a drop of blood from different animals, varies to an extraordinary degree; and, thirdly, because different animals have a different degree of susceptibility in regard to the germs of the same dis-

ease. In other words, just as there is a *vis medicatrix naturæ* which enables a certain number of the individuals in which disease-germs have multiplied to overcome such germs and to recover from contagious diseases, so there is a *vis conservatrix naturæ*, by which not only a certain number of individuals resist the germs of any given disease, but which enables every individual to resist a certain number of these germs.

When, in the summer of 1880, I commenced my investigations of the effect of inoculations with diluted virus, I soon became convinced that, to obtain definite and comparable results, it was necessary to obtain a virus of a standard strength and one free from coagula and other foreign particles which prevent the even diffusion of the virulent granules. In these experiments, fowl-cholera was the disease selected, not only because it is an excellent type of the non-recurrent contagious fevers; but also because the virus is easily cultivated outside of the body, the subjects are cheap and easily obtained, and the Department of Agriculture, with which I am connected, was anxious for an investigation in the interests of our agricultural population.

The production of a virus which should contain a practically constant number of disease-germs in every drop, which could be obtained at will and in any desired quantity, which should be free from foreign particles, certainly seemed, at the time I am referring to, a most difficult question to resolve. But, fortunately, the obstacles to our success, as so frequently happens, did not prove so insurmountable when we came to grapple with them as they had appeared when contemplated from a greater distance. The germs of this disease were easily cultivated in a broth made from the flesh of fowls, which was carefully filtered until perfectly limpid and sterilized by heat. A few germs placed in a flask of this liquid, multiplied for a certain time and then became inactive. Pasteur demonstrated that this cessation of activity was due to the exhaustion of the available nutriment. What, then, would be easier than to make a broth of a definite strength by extracting the soluble parts of a given weight of flesh with a given quantity of distilled water? If we cultivate our germs in such a broth, at a favorable temperature, we should always obtain, at the moment when the nutriment is exhausted, a virus of practically identical strength. This reasoning, I may add, has been fully justified by the many experiments which I have made with a standard virus prepared in this way.

The number of germs in a drop of such standard virus, I have never accurately determined, but I assured myself at an early stage of these researches that there were over one million six hundred thousand.

It was not until the 13th of May, 1881, that my methods of investigation were sufficiently perfected to allow the inauguration of a series of experiments by inoculating with dilutions of a standard virus. The inoculations always consisted of a single lancet puncture, and as much of the virulent liquid as would adhere to the grooved lancet was inserted between the skin and the muscles beneath the wing.

It will be necessary for me to refer here to some symptoms of this disease, in order that the reader may better appreciate the results of these experiments. Owing to some anatomical and physiological peculiarities of birds, the secretions of the kidneys are added in the cloaca to the feces. The kidney secretion of birds is of a semi-solid consistency; it is in health perfectly white and is seldom intimately mixed with the bowel contents. This white secretion of the kidneys, which for convenience I call the urates, is easily seen and examined in the droppings. The very first symptom which is seen after inoculation with strong fowl cholera virus is a slight yellowish coloration of the urates, due very probably to disturbance of the liver, as this organ is the one most constantly and most intensely affected in the disease under consideration. A day or two later, the droppings are more frequent and consist almost entirely of

¹ I hope that the opponents of the germ theory will forgive me for assuming that the organisms seen in virulent liquids are disease-germs, for it would be manifestly impossible for me to enter into a discussion of this question in the present article.

the yellowish urates mixed with an increased proportion of liquid. The fleshy parts about the head now become pale and bloodless, the temperature rises four or five degrees, the appetite is lost, the bird becomes dull, stupid, sleepy, and finally dies within two or three days from the first symptoms.

May 13, 1881, I inoculated four fowls with diluted virus; for one the dilution was 1 to 50; for the second, 1 to 500; for the third, 1 to 2,500; and for the fourth, 1 to 5,000.¹ With the first one the urates were slightly tinged for a day or two; with the second the urates were deeply colored, and there was loss of appetite for a few days; with the remaining two the urates showed no signs of coloration, nor was there any apparent change in the perfect health of these birds. The most important result of the inoculations was a slight circumscribed inflammation, which was noticed in each case at the point of inoculation the seventh day after the operation. This local lesion is very apparent from the increased size of the blood-vessels, and a noticeable swelling from one-fourth to three-fourths of an inch in diameter.

At the time of these experiments, I underestimated the importance of the lesion just described, for, while I thought it possible that a slight degree of immunity might be obtained by means of it, I could not conceive that a complete insusceptibility would result without the yellow urates and other symptoms of a constitutional affection. That is, it was naturally expected that a mild attack of the fever was necessary to protect against the subsequent recurrence of the disease.

Being desirous of producing the general fever of as mild a type as possible, I now inoculated four fowls with the same virus diluted as 1 to 1,000. What was my surprise to see each one of these birds succumb to the disease in its most virulent and fatal form! I was now brought face to face with the great obstacle which has always prevented the physiological investigator from developing an exact science, and which had proved an insurmountable difficulty to those who had previously attempted this line of investigation—that is, the individual peculiarities of living animals.

It was not to be supposed that the birds in the first experiments escaped because no germs were introduced with the diluted virus, since in a dilution of 1 to 2,500 there would be more than 600 germs to every drop, and in the dilution of 1 to 50 these would be increased to more than 30,000; besides there was the local inflammation which developed after the punctures had healed, and with two of the birds a sufficient coloration of the urates to denote constitutional disturbance.

My experiments have demonstrated, conclusively, that susceptibility and insusceptibility are only relative and never absolute conditions. A certain proportion of fowls will resist inoculation with a drop of strong virus, but if we increase the dose to ten, twenty, thirty, or sixty drops, even these may be made to contract the disease. As we decrease the dose to one-fiftieth, one-five-hundredth, one-thousandth of a drop, we find that the proportion of fowls which contract the affection becomes continually smaller and smaller. Measuring the susceptibility of fowls by means of this diluted virus, we find that it varies to an enormous extent with different individuals. In one case a bird died from inoculation with one-forty-thousandth of a drop, while another resisted the enormous dose of one drachm, or about two and one-half million times the former amount.

We will now return to our experiments in the production of immunity. The 2d of June, 1881, the two birds which had been inoculated with dilutions of 1 to 50 and 1 to 500 and recovered, received an inoculation with pure standard virus, while the two which had been inoculated with dilutions of 1 to 2,500 and 1 to 5,000, were tested with a dilution of 1 to 500. Not one of these inoculations produced the least effect; the punctures healed

and remained free from irritation as though no virus had been inserted, and the general health was not in the least disturbed.

On November 7, 1881, I inoculated two fowls with a dilution of 1 to 2,500, two others with a dilution of 1 to 5,000, two others with a dilution of 1 to 10,000, and two others with the undiluted virus. The last two died, as did one from each of the first two lots. The remaining four birds had a well-marked local lesion, but no constitutional disturbance, and remained in the best health. December 6th, all were inoculated with a dilution of 1 to 500. This producing no effect, either general or local, they were reinoculated December 13th with undiluted standard virus. Two now showed more or less coloration of the urates, but no other signs of ill health; the appetite and general appearance were perfect throughout the experiment.

Ten fowls were inoculated November 28th with a dilution of 1 to 10,000. Of these, three died, two had mild attacks and recovered, while five had the local lesion with no general symptoms. December 21st, the seven birds which recovered from these inoculations were inoculated with the strongest virus. This was followed in one or two cases with yellow urates, but there was no loss of appetite or dulness, and all remained in excellent health.

Up to this time more than eighty birds have been inoculated with diluted virus, though, as the remaining experiments have only recently been communicated to the Department of Agriculture, it would be premature for me to publish details at present. I may say, however, that with dilutions beyond 1 to 100,000, I have had no results, and it appears that inoculations with dilutions of 1 to 80,000 would give the local lesion and immunity to the most susceptible birds, and that the remainder could then be safely inoculated with a dilution of 1 to 10,000, which would grant immunity to all or nearly all. The experiments are still too few, however, to enable us to be perfectly certain in regard to the strength of virus to use with the greatest safety. The birds protected in this way have not only been tested with strong virus, but they have been placed in infected runs with sick birds, and in no case has there been a failure to resist the contagion.

From these experiments a number of exceedingly important conclusions may be safely drawn:

First.—A single disease-germ cannot produce this extremely virulent disease; it cannot even multiply sufficiently to produce the local irritation at the point of inoculation. When a quantity of virus was introduced into the tissues, which should have contained at least twelve germs, there was no effect, either general or local, but by increasing this one-third with the same birds, the local irritation appeared.

Second.—It is apparent that the local resistance to the germs fails, while the constitutional resistance may still be perfect, and that in this case there may be a local multiplication of the organisms for two or three weeks without any disturbance of the general health.

Third.—That this local multiplication of the virus is sufficient to grant a very complete immunity from the effects of such virus in the future.

From these conclusions it follows that the most virulent virus may be diluted to such an extent as to become practically a vaccine, and that in this condition it may be used safely for producing insusceptibility.

These facts are not exactly what we should have expected from theoretical considerations, but unless I am greatly mistaken, they are on this account, even, destined to modify our ideas very materially as to the general principles underlying the contagia and the contagious fevers. At present I can do no more than refer to this aspect of the question, leaving the practical applications to suggest themselves, as I believe they will, to every one who ponders over the many mysteries connected with the phenomena of this class of diseases.

¹ Details of these experiments will be found in the Report of the Department of Agriculture for 1881 and 1882, p. 285.

Interesting and important as the results I have detailed evidently are to the veterinarian and the agriculturist, they would be more or less out of place in this journal, were it not for the probability that the germs of the contagious fevers in men and animals are very closely related organisms, that the mysterious condition of the animal body, which we call insusceptibility, is comparable from all points with the insusceptibility of mankind, and that the methods by which we can grant immunity to animals are equally applicable to the human subject. From this standpoint it at once becomes a matter of importance to learn if the diluted virus of other contagious fevers of animals produces either a milder affection or a harmless local irritation also ending in immunity; in other words, is our method of vaccination, with a small number of very virulent germs, generally applicable to the various diseases of this class?

In April, 1881, M. Chauveau¹ announced the result of experiments made with charbon virus, by diluting virulent blood until each cubic centimetre contained from fifty to one thousand rods of the *Bacillus anthracis*, and injecting this dose directly within the jugular vein. He did not state how the number of the germs was estimated, and one would suppose that this would be rather a difficult matter to accomplish with any degree of certainty, unless, indeed, an apparatus similar to that used for counting blood-corpuscles was at hand. M. Chauveau believed that by introducing the germs directly into the blood-stream there would be less danger of a fatal result—a supposition which may be contested from the results of my experiments. In his first experiment four sheep received a dose of one thousand bacilli each. All died of charbon. In the second experiment, two sheep received about six hundred bacilli each. One died of charbon; the other did not show the least symptom of disease. In the third experiment, one animal received fifty and the other one hundred bacilli. To the liquid containing the larger number one per cent. of carbolic acid was added. No effect was produced by the carbolized virus; the other animal had a very slight fever of short duration.

The animals remaining from the second and third experiments, and two others, in all five sheep, received, seven days after the third experiment, a dose containing about one thousand bacilli. All died of charbon; but the one which had showed slight symptoms of fever in the third experiment did not die until the seventh day. The death of this animal was due to a bacterial meningo-encephalitis—being the usual result of inoculating partially insusceptible sheep with large quantities of virus. It seemed, then, that this one animal had acquired a certain degree of immunity.

In the fifth experiment, five sheep received about two hundred and fifty bacilli each. All recovered after presenting slight and transient symptoms of fever. Re-inoculated, six weeks later, with strong virus, four resisted perfectly, while a single one died. In this experiment, the first virus used was taken from a rabbit which had been dead several days, though perfectly preserved because of the cold weather. We know, however, from Pasteur's experiments, that when the bacilli are preserved, either at so high or so low a temperature that they cannot form spores they rapidly lose their virulence, and, as in this case the strength of the undiluted virus was not tested, there is some reason to doubt if the dilution should receive the entire credit of the results.

In the same communication, M. Chauveau records an observation with the virus of *charbon symptomatique*, which corresponds to the black quarter of this country, and is entirely distinct from charbon. This virus, though one of the most active known, may be injected into the veins in considerable quantity without causing death; but a very much smaller dose in the connective tissue infallibly destroys cattle and sheep. In December, 1880, ten sheep had been collected, which, from many preven-

tive inoculations with charbon virus, had obtained a very complete degree of immunity from this disease. Before receiving their final test, they were to have a last preventive inoculation with one cubic centimetre of liquid extremely rich in bacilli. By mistake, this liquid was filtered through a cloth that had served in preparing the virus of *charbon symptomatique*. This cloth had been washed, but a sufficient quantity of virus remained in it to produce the disease in each of the ten sheep. The virulent liquid was drawn with the syringe from a high and narrow vessel, so that for each animal it came from a different depth. The results were in proportion to this depth, being mildest with the first and most severe with the last. The first four recovered, while the remaining six died. A month later, an inoculation was made in the other thigh, of those which had recovered, with a considerable quantity of black quarter virus. The resulting symptoms were very mild, but not equal with all. Those which suffered the least by the former inoculation were more intensely affected by the latter.

The observations of M. Chauveau are undoubtedly very important if we look upon them as confirming the doctrine of attenuation by dilution, but of themselves they are plainly insufficient to establish this doctrine with either of the diseases with which they are connected. With charbon all the indications must be drawn from the last experiment, and this was made with virus of doubtful activity. The observation with black quarter virus was not a premeditated experiment, there was no intention to inoculate with this virus, and, consequently, it cannot carry the weight of a genuine experiment. At the same time, viewed in the light of my results with fowl cholera, these experiments with charbon and the observation with black quarter are sufficient to show that these viruses are subject to the general law which my experiments were first to demonstrate.

Still more recently, M. Peuch,¹ Professor at the Toulouse Veterinary School, has made experiments in the same direction with the disease known as sheep-pox. This is a form of variola peculiar to sheep and extremely fatal to these animals. It has been combated in the north of France by inoculation, but in the southern departments the losses from this operation were so nearly equal to those caused by the spontaneous disease that the practice has been about abandoned. As the danger in this disease is principally due to the eruption, and as M. Chauveau in his experiments with vaccine had granted immunity to cattle by hypodermic injection of virus without producing any specific eruption, M. Peuch conceived the idea that by reducing the number of germs by dilution, and injecting the liquid beneath the skin a similar result might be obtained with sheep-pox. His recorded experiments have been made with seventeen sheep. Eight were inoculated with a dilution of 1 to 20, four with a dilution of 1 to 30, and five with a dilution of 1 to 50. The inoculations with the strongest virus (1 to 20) produced a general eruption, which followed the regular course. But with the weakest virus, injected in half the quantity, the effects were less marked. With five sheep inoculated with eight centigrammes of this dilution a single one presented a very mild secondary eruption, three had a pustule at the point of inoculation, the fifth had only a slight swelling at this point. All acquired immunity.

These experiments, like Chauveau's, are not sufficiently numerous to demonstrate a great principle, but they are one more and a very important contribution to this end. In the methods of both of these gentlemen, there is much to be desired before they could be applied in practice, especially to such virulent diseases as fowl cholera, with which a single drop of a dilution of 1 to 40,000 sometimes causes death. The strong virus which they use varies greatly in strength, it contains coagula and animal *débris* which prevents its even diffusion; it is in many

¹ Comptes Rendus, ser., 1881, p. 844.

¹ Recueil de Médecine Vétérinaire, 1882, p. 977.

cases difficult to obtain when desired. By my method the virus is obtained of a definite strength; it may be preserved for an indefinite length of time in cultivation tubes, and in a short time can be increased to any desired quantity. These are points which, especially in endeavors to control the diseases of mankind, must be considered of the greatest importance.

In presenting a new method for attenuating the active viruses of contagious diseases, it is, of course, desirable to know how it compares practically with the method of M. Pasteur which has recently received so much attention, and which, in spite of adverse criticism, must be accepted as a remarkable advance in medical science. It has not been unusual for men who stand quite high in scientific circles to speak of Pasteur's method as though the mitigation in this case was produced by dilution; others of equal eminence have told us that it consisted in passing the virus through a large number of cultivations. In reality, it is neither the one nor the other. Pasteur's first attenuation was made with fowl cholera virus, and his method with the later ones has only been changed to suit the peculiarities of the virus of other diseases. With fowl cholera a cultivation of the virus was made in sterilized broth, the flask being arranged to admit filtered air. This was set aside for an indefinite period, varying from five to eight months, during which time the attenuation occurred. A second cultivation, made from this first one after this indefinite period, was the vaccinal virus. During this time the activity of the germs is gradually lessened, but the same degree of attenuation does not always occur in the same length of time; and when preparing fresh vaccine the degree of attenuation must be determined by inoculation experiments.

When the vaccine is once obtained it may be preserved for a considerable time by frequently renewing the cultivations of it, but this cannot be done indefinitely, as Pasteur at first announced. This vaccine gradually loses its strength, no matter what precautions are observed; consequently, it must from time to time be renewed, the setting aside for from five to eight months, and the testing of the activity, which involves much trouble and expense, to say nothing of the skill required, all must be gone over again as at first. What makes this still worse, there must be two vaccines, one stronger than the other, because the weaker vaccine is too inactive to grant complete immunity.

With charbon virus, the attenuation occurs more rapidly, being complete in less than eight days for the weaker vaccine; but here there is also an obstacle to its preparation. The virus must be kept at a constant temperature of 42° to 43° C. to prevent the formation of spores. If spores are formed, there is no attenuation and the vaccine obtained will produce fatal effects. Koch and Klein have each attempted to show that virus could not be attenuated in this way; but they undoubtedly failed by allowing spores to form either by variation of the temperature, by the liquids being too shallow, or from neglecting to supply some other required conditions. These experiments, while they cannot overthrow Pasteur's general conclusions, are sufficient to demonstrate the difficulties and the uncertainties of the method when attempted by others less skillful than the originator.

With the method of attenuation by dilution, as I have developed it, most of these difficulties are avoided. The preparation of the standard virus and its dilution can be accomplished, with fowl cholera at least, within twenty-four hours from the time the particle of blood which originates it is taken from the affected animal. The stronger the virus, the longer will it retain its full activity, and, hence, the unmitigated virus is in far the best condition for preservation, and the dilution can at any time be made in a few minutes.

Again, the method of Pasteur cannot well be applied to human diseases, because it requires too many experiments to learn the degree of attenuation. In some

cases, the attenuation does not occur until a few hours before the death of the virus, while in other cases it may be weeks or months before. So that, in applying it to a new disease, there are no indications except those furnished by inoculation experiments. On the other hand, if we dilute we know that we attenuate. If we introduce but ten or twenty germs of almost any disease the probabilities are that the effect would be very slight; if such an inoculation were unsuccessful, the number could be gradually increased. Surely when many people are exposed to a deadly plague, it would not be impossible to pursue this class of investigations. Of course, I only mean the above remarks to apply to those non-recurrent fevers from which immunity may be acquired within a few days or weeks.

Whether I am right or wrong in considering that this method of preventive inoculation may, under certain circumstances, be used advantageously in controlling the plagues of mankind, it seems to me that the method by dilution has some incontestable advantages over the method of Pasteur. I may summarize these as follows: 1. The virus is obtained by a definite strength. 2. It may be preserved in the condition in which it retains its activity the longest time. 3. The attenuation requires but minutes instead of weeks or months. 4. The experiments to learn the proper degree of attenuation are less dangerous to the individuals operated upon. 5. These experiments once made, it is not necessary to repeat them with every fresh lot of virus. 6. One virus and one successful vaccination are all that is required. 7. The amount of virus needed is many times less than with other methods. Certain disadvantages will doubtless be revealed by the experiments of the future, but their importance cannot be foretold.

I should not be surprised if greater advances are made by the investigations of the future, for the prevention of contagious diseases, than have been accomplished in the past, possibly vaccination in all forms may be discarded, but at present the question is fairly before the medical profession—Shall we vaccinate with a large number of comparatively inactive germs, or with a small number of those which retain their greatest virulence?

The solution of such a question can hardly be made from theoretical considerations, it may even require investigations which include a large number of individuals, scattered over a considerable territory and embracing a variety of diseases; but, with the principles upon which these methods depend for their success once understood by our scientists, it cannot be long before we have the elements for a complete and satisfactory conclusion. At the same time, it is not to be forgotten that the method by dilution, because of the little time required to prepare the virus, might often be resorted to when the other would be impossible.

In conclusion, I would call attention to the following points of this communication, which are believed to be original:

First.—The method of producing a virus of standard strength.

Second.—The fact that germs which usually multiply throughout the whole body may be compelled to limit their reproduction to the point of inoculation by reducing the number inserted.

Third.—That this local multiplication grants an immunity from the disease in the future.

Fourth.—That a very small number of germs may be introduced into the tissues with impunity, and are not able to produce the least effect, either general or local.

GRANULATED MILK is made by subjecting milk to a temperature of 130° until the watery part has been evaporated. It is then granulated and sugar is added, when it looks like corn meal. The evaporated milk is not as solid as condensed milk, and when water is added it cannot be distinguished from natural milk.

THE INFLUENCE OF EXTREME LATERAL CURVATURE OF THE SPINE UPON THE COURSE OF LABOR.¹

By W. M. POLK, M.D.,

* PROFESSOR OF OBSTETRICS, MEDICAL DEPARTMENT UNIVERSITY OF NEW YORK.

THE following case is one so interesting to me that I cannot forbear presenting it to you to-night. In June last a lady seeking my services as an attendant in her first confinement, asked that I make an examination of her pelvis, that she might know whether any difficulty in labor was to be apprehended. She was moved to this by the fact that she was the victim of decided lateral curvature of the spine, a state of things which had existed for some years.

I made a very careful examination of the pelvis, and finding it of normal dimensions expressed myself as satisfied that all would go well in the coming labor.

She then told me that before marriage she had sought the same opinion from one of the most distinguished and careful obstetricians in our city, and he, after a careful examination, had expressed himself precisely as I had done. Thus reassured she went forward to confinement with all confidence. The sequel showed, however, that matters were not to end so smoothly as all had expected.

On Friday evening, in the latter part of December, she sent for me, as labor had commenced. I found her in excellent condition, mentally and physically. A vaginal examination proved that labor had just set in. The cervix was rather higher than is usual even in a first labor, and the os was somewhat nearer the left pelvic wall than to the right, showing right lateral obliquity of the uterus. This, to some extent, being almost a normal condition. I attached but little importance to it. The patient now called my attention to the position of the fundus. An examination of the exact position of the uterus was now made, and it was seen that the obliquity was somewhat excessive. An attempt to push it toward the median line revealed the fact that it could not be placed and held in normal position without causing more pain than the patient was willing to bear. The resistance came from the left side of the abdominal wall and the left free border of the ribs. Inquiry showed that for three months the uterus had gradually been pressing more and more toward the right, and for some weeks past had caused a decided bulging of that side. As she expressed it, she had been carrying the child on the right side. Thinking position would correct the defect, she was advised when resting to lie on the left side.

Friday night, Saturday, Saturday night, Sunday, and Sunday night were passed, and still the patient was not delivered.

Until Sunday night at twelve, her condition was excellent, the pains though regular were feeble. Under the influence of morphia she had sleep Saturday night and Sunday. The condition that existed was "tedious labor" to an aggravated degree. An observation taken at 1 A.M., Sunday night, showed the membranes intact, the os about the size of a trade dollar, soft and dilatable, still out of the median position. Uterine contractions were regular, but short and inefficient, the organ seemed to be acting at a disadvantage. A catheter was introduced into its cavity, and allowed to remain half an hour, the result was to strengthen its action, but still no progress was effected.

The condition of the child was excellent, but the mother began to show signs of exhaustion. The pulse stood steadily at 110, and the temperature had reached 100 $\frac{3}{4}$ °. It was evident that the woman could not deliver herself, that dangerous symptoms were appearing, and that the pathological condition present was tedious labor, due to inefficient uterine action. The cause of the faulty action was evidently right lateral obliquity of the uterus, and this in turn was directly due to the lateral curvature of the spine and its accompanying pelvic deflection.

This conclusion was reached only after a careful consideration of all that was before us. Tedious labor was certainly present, *no other cause of such a labor save lateral obliquity was present*. The inclination of the uterus was such that the plane of the os looked toward the middle of the left pelvic wall, while nearly the entire fundus lay to the right of the median line, so that a rough estimate of the uterine axis, made at the time, found it to correspond to a line running from the centre of the left ischium to a point about three inches to the right of the umbilicus. The organ was freely movable, and no other tumor was to be found in either the pelvis or abdomen. All attempts to place it squarely over the pelvic inlet were prevented by the position of the free border of the ribs on the left side, aided by the tension of the muscles attached thereto. The spine was curved laterally to an extreme degree, the dorsal convexity looking to the right, the lumbar to the left, the left leg was half an inch shorter than the right, and the pelvis was displaced so as to meet, and as far as possible correct the deformity. The right side was thrown up and forward, consequently the left was lowered and thrown back, making the axis of the superior strait strike the abdominal wall to the left of the umbilicus. The distance from the free border of the ribs to the iliac crest was one and one-half inch shorter on the left side than on the right. In other words, the deformity present was an extreme form of the more common variety of lateral curvature of the spine.

By looking at the diagram it will be seen at what great disadvantage the uterus was placed, the position of the ribs on the left side had evidently thrown it over to the right, while the centre line of the pelvic inlet had been displaced to the left, the two conditions not only intensifying, but tending to maintain the uterine obliquity. The observations upon the spine, thorax, pelvis, and leg were carefully verified after confinement, both upon the patient and by reference to the Case Book of Professor Lewis A. Sayre, who kindly granted me access to it, the lady having formerly been under his care.

From all this I was able to verify the opinion formed at the time of labor as to the

nature of the difficulty and its course. It was a case of tedious labor, due to uterine obliquity, which in turn was due to lateral curvature of the spine. The obliquity could not be easily corrected because of the position of the free border of the ribs on the left side.

As said above, the woman could not deliver herself, making it necessary to apply the forceps. The os was dilated so as to apply the instrument within the uterine cavity. Some little traction was needed to get the head well into the canal. After a while this was accomplished, and all seemed going well. By the time the head reached the floor of the pelvis the uterus had shifted its position over to the left of the median line. Suddenly violent contractions set in, and, though the patient was completely under the influence of chloroform, the head was driven out so rapidly I could not remove the forceps, a ruptured perineum being the result. This was repaired, and for a few hours it looked as if we would have a favorable termination of the puerperal period, but the persistent elevation of temperature dispelled the hope. For three weeks we battled with a stubborn attack of puerperal fever, finally carrying the patient to a complete recovery. Such is the record of this case. That all questions as to the possibility of some deformity of the pelvis being present may be met, I will say that in addi-

Explanations—S, spinal column; A, B, plane of pelvic inlet; C, D, axis of pelvic inlet; E, F, axis of uterus—down.

¹ Read at a meeting of the Practitioners' Society of New York, February 2, 1883.

tion to the examinations made before and after labor, I took advantage of the anæsthesia to explore the canal with the hand in the vagina. This, together with careful external measurements, showed that the pelvis in itself was normal.

Uterine obliquity as a cause of tedious labor is mentioned in every work on obstetrics; but the variety mentioned is that in which, owing to relaxation of the abdominal muscles, the uterine axis is not held in coincidence with the axis of the pelvic inlet. Such a condition is one remedied easily by external pressure and position. Neither of these sufficed here, owing to the causes mentioned making the case one of great danger, calling for the introduction of the forceps through an incompletely dilated cervix, and the delivery of the head from above the superior strait, the high forceps operation. It would seem, then, that extreme lateral curvature of the spine, even with a normal pelvis, is a condition likely to seriously affect delivery.

I am at a loss to account for the fact that such cases have not been observed and reported frequently, for the reason that lateral curvature is so common. I can only imagine that such extreme cases as this, complicating pregnancy, are not common, else our works on obstetrics would not be so free from all allusion to them as now appears.

The condition of contracted pelvis with lateral curvature is known and dwelt upon, but lateral curvature is not recognized. One always feels hesitation in reporting a case which may appear to suggest that his observation may have been more acute than that of others; therefore I do not ask you to accept my conclusions; I only ask you to consider them for what they may be worth.

EXHAUSTION OF BRAIN-ENERGY.

By J. LEONARD CORNING, M.D.,

NEW YORK.

INTIMATELY associated with, and often the direct outgrowth of insomnia is a condition which manifests itself by a greater or less degree of impairment of cerebral energy, more particularly in the domain of the psychical functions. Those who suffer from this disorder complain that they are quite unable to perform the usual amount of mental work; that they are easily fatigued by a continuation of the same employment for any length of time; that the memory for remote as well as recent events has become unreliable; that society has become distasteful to them; that ambition has deserted them; that they are frequently and even profoundly depressed. Sometimes they complain of fatigue upon even the slightest bodily exertion, but very often there is no impairment of the motor functions whatever, and the disturbances are purely psychical in nature. Sometimes those afflicted by this disorder are the victims of various forms of morbid fear. This fear may be directed toward extraneous sources or may confine itself to the individual economy. In the first instance it may manifest itself in a vague dread of being left alone, in a dread of society, in a fear of open or exposed places or of circumscribed localities. Again, there may be an ever-present fear of pecuniary calamity or a dread of a possible loss of social status, etc.

Where the attention of the sufferer is directed toward himself, the symptoms often assume the form of hypochondria. The individual imagines that his liver or some other organ is diseased, that he is about to become insane, that he is about to suffer from a stroke of paralysis, or that he has entered upon some form of insidious malady, which is sure to result in death.

It is very necessary, however, that the physician should use the utmost caution before ascribing importance to apprehensions of these persons. Usually these fears have only a subjective significance, and are purely

the outgrowth of a morbid condition of the mind mechanism.

Otherwise to be considered are those symptoms which point directly toward those organs enclosed within the cranial cavity. Those symptoms are: (1) Great weariness upon the slightest mental exertion, and often total inability to work at all; (2) pain in the region of the vortex following even slight mental work; (3) sometimes frontal headache; (4) tenderness of the scalp; (5) a feeling of constant weariness; (6) disorders of memory; (7) impairment of will power; (8) sometimes occipital pain, which not infrequently disappears after a few applications of the faradic current; (9) morbid excitability, which often assumes the form of violent anger upon slight provocation; (10) very great depression, particularly during the early morning hours; (11) disorders of the cerebral circulation, which may sometimes assume the form of congestion, sometimes of anæmia, or sometimes the two conditions may alternate with each other. In any event the vascular derangements, although, doubtless, of secondary origin, deserve especial attention on account of the baneful effects which they in their turn exercise upon the already demoralized condition of the central ganglia.

In brain-exhaustion we have to do with a condition of the ganglia in which the processes of disintegration have outstripped those of integration, a condition in which the ganglia are no longer able to hoard up the usual and requisite amount of explosive energy. Exhaustion of brain-energy is, therefore, the outgrowth of defective nutrition, primarily inaugurated by an illegitimate demand upon available brain resources. It is the state engendered by an excess of demand over supply.

Treatment of exhausted brain-energy by prolonging the duration of brain-rest.—If, then, brain-exhaustion be that condition of the organ in which the mechanism of supply has become more or less defective, the problem presented for therapeutical solution is how best to bring the supply of brain-energy up to the normal standard. I know of but one method of accomplishing this end, namely, by decreasing for a time the expenditure of cerebral energy to a minimum, and increasing the amount of available cerebral force. By prolonged sleep it is possible for the ganglia to hoard up, in spite of the defective mechanism of supply, an amount of energy proportionate to the comparably reduced output of brain-force. Thus, by slow degrees, the proper co-relation between integration and disintegration may be re-established. But it is utterly useless to hope for such a result at once, as, when the perverted nutritive conditions have once become established, nothing short of prolonged brain-rest can by any possibility result in the re-establishment of the normal nutritive processes of the cell economy. In many instances of brain-exhaustion there is present a condition of anæmia, which calls for a tonic treatment. Sometimes, however, the general bodily condition is excellent, and there is no organic or even functional trouble discoverable excepting the morbid cerebral manifestations described above. In these, and in fact in a large number of cases of impaired brain-energy, general faradization and central galvanization often aid materially in treatment. Where there are marked derangements of the function of sleep, and where the insomnia is not attributable to gastric or other visceral disturbances, sedatives may be employed with good results in combination with the Turkish or hot bath. The reaction from these baths is, however, often too great to be borne by very sensitive patients. In such cases recourse may be had to tepid baths. The best soporific effects from baths are obtained shortly before retiring, and they should be prescribed at this time, do circumstances admit of it. Exercise is another important element in treatment, but should never be carried to excess. The effects on sleep induced by horseback riding or a brisk walk are often quite remarkable. In the treatment of those cases of cerebral erethism, in which a morbid degree of irritability is present during

the day, the bromides play a conspicuous part. The dose will depend somewhat on individual idiosyncrasy, but five or ten grain doses will often be found to answer.

Where there is a marked determination of blood to the head, cold baths should not, as a rule, be resorted to. On the other hand, a warm bath to the body and ice-bag to the head, will often be found to render the greatest service.

A change of climate is often very beneficial in these cases, more particularly from the seaboard to an elevated and dry atmosphere.

Sometimes benefit is experienced from the administration of ergot in large doses, but the effects of this drug are not constant. Where gastric derangements are present, these cases are very materially complicated, and nothing very permanent can be hoped for until the stomachic conditions have been sufficiently improved to render an amelioration in nutrition possible.

In a more extended consideration of this and allied subjects ("Brain-Rest," Putnam's Sons) I have devoted considerable space to the discussion of the various therapeutical questions connected with sleeplessness, on account of the intimate relationship which subsists between disturbances of sleep, insanity, and functional brain-trouble.

Reports of Hospitals.

BELLEVUE HOSPITAL, NEW YORK.

(Reported by ROBERT T. MORRIS, M.D.)

A CASE OF DISLOCATION OF THE SCAPHOID AND OS MAGNUM.

ON January 20, 1883, Frank M—— came to Bellevue Hospital as an "office case," to be treated for an injury which he had received seven days previously; he having caught his right hand between a heavy brush and roller, which are used in polishing paper, and having forcibly extricated it.

On making an examination I found the hand strongly adducted and rotated inward, with an unnatural projection at the carpus anteriorly. At the fourth metacarpophalangeal articulation there was also a marked deformity. In addition to the above the whole radial side of the thumb was denuded of cuticle. On account of the tension exerted by the muscles of the forearm, which the patient kept firmly contracted, it was difficult to make a diagnosis, and he was placed under ether, the nature of the injury thus becoming apparent. The scaphoid and os magnum were dislocated anteriorly and the semilunar, although not out of place, was freely movable. The fourth proximal phalanx was also dislocated anteriorly from its metacarpal bone. The dislocations at the carpus were easily reduced after pressing the semilunar forward slightly, and there was no difficulty in replacing the phalanx.

On allowing the patient to come partially out from under the influence of the ether, the dislocations at the carpus were immediately reproduced, so that it was necessary to readminister the anæsthetic. This having been done, and the bones again put in place, anterior and posterior splints were applied, and the hand bandaged in such a way that the tendency to adduction would be overcome.

Passive motion to all of the fingers except the fourth was begun in a few days, and continued until the splints were removed, nearly four weeks later. Passive motion at the wrist and to the fourth finger was then proceeded with, and at the present time (March 12th) the patient has a fair amount of voluntary movement at the carpus, as well as at his injured finger-joint.

The mechanism of the injury to the wrist would seem to be as follows: The patient throwing himself violently backward in order to extricate his hand from the ma-

chinery, probably ruptured the external lateral ligament, and portions of the anterior and posterior ligaments of the carpus, the dislocation of the bones occurring secondarily. The ligaments connecting the dislocated bones together and to adjacent bones were probably ruptured also, as the scaphoid, os magnum, and semilunar were individually freely movable. (There was no fracture of the radius.) Whether the dislocation of the phalanx took place secondarily to rupture of its ligaments, or whether the bone in being forced out of place ruptured its ligaments, it would be hard to say.

Progress of Medical Science.

INTESTINAL MOVEMENTS.—Nothnagel, in a recent lecture (*Canada Medical and Surgical Journal*, March, 1883), gave a detailed account of some valuable experiments which he has performed in connection with this subject. His method of investigation was to keep chloroformed animals, with their abdomens opened, immersed in a bath (100° F.) of a half per cent. solution of common salt. He has demonstrated by this method that, in animals at least, no peristaltic actions occur in uninjured intestines. The effect of injections into the rectum was examined, colored fluid being used. It was found that a small quantity of water had no effect on the peristalsis. A considerable quantity distended the rectum without exciting any action. Iced water caused action sufficient to move the fluid from 15 to 20 cm. up the bowel. Olive oil had a similar action. A strong solution of common salt, forced up by a syringe a distance of 10 cm., was carried up, together with a mass of feces, by the antiperistalsis to the cæcum. Similar results were obtained by using concentrated solutions of nitrate of potash and bromide of potassium. The common salt injections always caused contractions, which passed both ways. In a case of ileus in the human subject, an injection of colored salt solution, which was used during life, was found, after death, to have reached the cæcum. The conclusions to be derived from these experiments are that, in intestines in a healthy condition, or containing only unirritating contents, peristalsis only occurs from above downward, and if there are any irritating substances in the bowel, antiperistalsis occurs also. To explain the occurrence of fecal vomiting in intestinal obstruction, ligature of the small intestines was resorted to. It was found that, unless irritating substances were introduced into the bowel, no ascending contractions occurred. When the intestine is ligatured, the part above becomes filled and the part below empty. Descending contractions are generally seen commencing at the stomach and terminating at the distended portion, and as the distention ascends higher and higher, the waves of descending contraction travel less and less, until finally they are limited to a narrow segment near the pylorus. There is no such thing noticed as antiperistalsis sufficient to bring about fecal vomiting. Its true cause is due to the action of the diaphragm and abdominal muscles. The paralyzing effect of distention of the bowel above the ligature proves clearly the well-known injurious effect induced by the use of purgatives in intestinal obstruction. By increasing the peristaltic contractions, they carry the contents of the intestines more rapidly and violently to the seat of obstruction, and in this way the paralysis which follows distention is more quickly brought about.

Nothnagel had many opportunities of noticing the occurrence of intussusception during the course of his experiments. The invagination always occurred from above downward, a part that was contracting strongly slipping into a portion that was at rest. He was often able to remove these invaginations by injections of salt, which set up an antiperistaltic movement. Morphia, in doses of from one-sixth to two-thirds of a grain, has the power of preventing the antiperistalsis induced by salt

injections, but if larger doses are given, from a grain and upward, then not only does the antiperistalsis appear, but in an aggravated degree. This anomalous effect Nothnagel ascribes to the small doses stimulating and the large ones paralyzing an inhibitory mechanism which is antagonistic to the nervous mechanism stimulated by a salt solution. This action is comparable to that of digitalis on the innervation of the heart, small doses stimulating and large ones paralyzing the inhibitory fibres of the vagus. The constipation produced by morphia is thought to be owing to a stimulation of a nervous mechanism which other experiments have located in the splanchnic nerves.

ON THE TREATMENT OF INFANTILE PARALYSIS.—Dr. Robert J. Lee calls attention to the very marked value of artificial heat in the treatment of infantile paralysis. This he illustrates by the case of a girl suffering from this disease in a severe form, who received no other treatment than hot sponging night and morning, and artificial heat to the affected limb, after going to bed. This limb was equal in size to the sound one eight years after the attack came on, although still paralyzed below the knee.

Dr. Wm. H. Barlow refers to the fact that artificial heat is an old therapeutic method in the disease in question. He considers it always necessary to protect carefully the paralyzed limbs, but believes that electro-therapy and voluntary and passive movements are much superior remedies to heat.—*Journal of Nervous and Mental Disease*, January, 1883.

MICROCOCCHI IN CEREBRO-SPINAL MENINGITIS.—At a meeting of a German medical society Dr. Leyden exhibited germs taken from a case of fatal inflammation of the membranes of the brain and cord. According to him, there is little doubt that meningitis is due to germs. Both Klebs and Eberth have observed meningitis after pneumonia, where micrococci were present in the sputum; indeed, Eberth detected the same germs in the fluid exuded from the inflamed meninges as he found in the pneumonic exudation; the same authority found micrococci in the pus, from a case of pyocephalus. In purulent fluid, found under the meninges of a school-boy, aged sixteen, Klebs discovered bacteria in active motion. Ebert claims to have observed, in the pus from traumatic cases of meningitis, germs of a different kind to those which he had found in septic cases of the same local affection. The question remains as to whether idiopathic meningitis, independent of wounds, pneumonia, or pyæmia, be a parasitic disease. Dr. Leyden believes that it is essentially due to micro-organisms. He bases his observations on a case under his own observation. A woman, aged thirty-five, was seized with violent vomiting in a railway carriage, on December 22, 1882. As she was stepping out of the carriage at the Berlin terminus, she was seized with a giddiness, and fell on the platform. Her face was bruised, and the membrana tympani of one ear ruptured, some fluid escaping. A few days later she was admitted into the Charité Hospital, with inflamed ear, violent headache, and constant sickness. After the other tympanic membrane had become perforated, and appropriate treatment adopted, the patient apparently recovered. At the end of last January all the symptoms recurred, with the more special symptoms of cerebro-spinal meningitis, rapidly proving fatal.

At the necropsy, the exudation over the pia mater of the brain and cord was found to be very abundant, the otitis had disappeared, and the perforation in each membrane had closed. In the fluid, hosts of micrococci of a perfectly oval form were found, oscillating freely, and rather larger than pneumonic micrococci. Some were solitary, some in pairs, some in chains.

In the discussion that followed Dr. Leyden's demonstration, Dr. Baginsky observed that, in children who had apparently recovered from cerebral symptoms after the rupture of one membrana tympani as the result of suppurative otitis, fatal pneumonia sometimes appeared

very suddenly in a few days, and this complication was probably due to micro-organisms. In Dr. Leyden's case there were symptoms of intracranial disease before the patient fell out of the railway-carriage; but then rupture of one membrana tympani occurred, discharge escaped, and thus clear evidence of otitis was proved by the accident. The distinction between uncomplicated otitis and mild meningitis is not always easy, and the first disease alone might have existed before the fall. The rupture of the membrane admitted air into a suppurating cavity; and the suspicion that the subsequent cerebro-spinal disease might have been a purely secondary affection is very strong. Dr. Leyden, however, believes that the micrococci of meningeal pus, as seen in this case, are more oval, but oscillate less actively than those of pus simply putrefied by exposure to air: in other words, he endeavors to prove that the meningitis was primary, and that the micrococci existed within the patient's body before the injury.—*British Medical Journal*, March 10, 1883.

MERCURY IN INTESTINAL OBSTRUCTION.—From an examination of a large number of cases, Bettelheim has come to the conclusion that the use of mercury in bulk (about seven ounces as a dose) is by no means a worthless remedy. On the contrary it sometimes saves life in cases of obstruction of the intestine, not yielding to other means, which are due to fecal accumulation, ascariæ, twisting or intussusception. No injury, and especially no perforation of the intestine is caused by it. He therefore recommends that after the use of the ordinary means, such as moderate doses of laxatives, opiates, irrigation of the intestine, changes in the position of the patient, electricity, and massage, mercury in bulk should certainly be had recourse to without fear.—*The Practitioner*, March, 1883.

INVERSION OF THE SEXUAL SENSE.—Under this title Charcot and Magnan (*Archives de Neurologie*, November 3, 1882) report six cases of imperative conceptions respecting sexual matters, which they consider allied to the sexual perversion of the Germans. The first case was that of a masturbator, a physician, who felt drawn to the anal region of females and clothed children for sexual gratification; the naked bodies were repugnant to him. He was disgusted with the idea of pæderasty and sexual intercourse; there was strong heredity in the case. In the second case there was also strong heredity, and the patient felt sexually attracted by the nails of women's shoes, concerning which he constructed elaborate romances and masturbated while gloating over these. The third case also had hereditary defect, and felt sexually attracted by white table-cloths, several of which he stole and was punished for so doing. The fourth patient, also a victim of hereditary defect, was unable to copulate with a woman unless her hair was dressed in a certain way, and she had a night-cap on. The other cases were victims of nymphomaniacal impulses. There is, it will be obvious, very little in common between these cases and sexual perversion as described by Gock, Servaes, Krüg, Krafft-Ebing, Ulrichs, and others. Dr. Hammond ("Diseases of the Nervous System") has described a case where shoes were the attraction, and Van Buren and Keyes ("Venereal Diseases") a case where a man was impotent except with women dressed in a peculiar style. As might be expected, impulses of this character are very frequent among hebephreniacs.—*Journal of Nervous and Mental Disease*, January, 1883.

SIR ERASMUS WILSON, although now in his seventy-fourth year, is not yet past work, his present studies being Egyptological. He is the President of the Biblical Archaeological Society, and Treasurer of the Society for the Exploration of the Buried Cities of Egypt. He is also one of the Court of Assistants and late Master of the Curriers' Company.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 7, 1883.

PROPOSED CHARTER AMENDMENTS AND THE HEALTH BOARD.

It is well known to many, if not to a majority of our readers, that there is now pending before our State Legislature a bill containing some radical amendments to our city charter, and which, if it becomes a law, will have the effect to reorganize our city government. Ever since the overwhelming Democratic victory achieved at the last election demands and promises have alike been made for such "reform" in the several departments as will both lighten the burden of the taxpayers, and at the same time secure a faithful and judicious administration of the functions of various departments sufficient to meet the public wants and merit the public confidence. With this motive in view Mayor Edson, several weeks ago, sent to the Legislature a bill providing for such amendments to the charter as would in his view meet the best interests of the city. It certainly had the merit of depriving politicians of their power to dictate or to interfere with the Mayor's appointments, and of placing the responsibility of the city's government where it properly belongs, in its chief magistrate. This feature not suiting the politicians, a substitute has been prepared in which the present power of the Board of Aldermen to confirm or reject the Mayor's appointments is retained, and which is openly declared to be for the benefit of a political party.

Now we do not propose to discuss in the columns of THE MEDICAL RECORD any political question whatever; but there are a few points in these proposed amendments to which we desire to call the attention of our readers.

A prominent feature of the bill is the provision for one headed commissioners in the city departments, with the exception of those of Charities and Corrections, of Police, and of Taxes and Assessment. This will remove our Health Department from its present efficient management, and place it directly under the control of political influence, to which we most seriously object. Whatever may be the result as it regards other branches of the city government, it must be acknowledged that the functions of the Health Department are too manifold and important to be intrusted to one man, and that man appointed for political purposes. The Board of Health is not only executive in its functions, but legislative and judiciary; that is to say it has the power of making ordinances, sitting in judgment upon nuisances and enforcing the sanitary laws. Questions often arise involving large property as well as sanitary interests, which

need careful consideration and full discussion before being finally decided. Emergencies are not infrequent where cool judgment is required, and heavy responsibilities assumed, and where interchange of opinion is important to intelligent action. These matters are all of too grave a nature to be exposed to the corrupting influences of political manipulations.

We very well remember when, some twenty years ago, the New York Academy of Medicine instituted a movement looking toward the rescuing of our public health matters from the hands of the crafty politician who then controlled them. We have not forgotten the health warden who defined hygiene as an offensive gas which rises from stagnant water. We remember how eminent physicians and sanitarians labored in this cause of sanitary reform until the legislation of 1866 was secured, which established the present system of health government, the efficiency of which was in a few months demonstrated by the masterly manner in which the outbreak of cholera during that summer was controlled, saving to the city hundreds of lives and hundreds of thousands of dollars. The same system is now in operation with such amendments as have from time to time been suggested by experience and advance in sanitary knowledge.

The Board of Health has to deal with an almost unlimited variety of nuisances. It is charged with the regulation of offensive trades, which involve large amounts of capital and industry. In settling the question of manure disposal and cattle driving, it was almost constantly at war with moneyed interests and political influence, while it is often obliged to call upon the courts to sustain its actions. It is charged with the care and treatment of contagious diseases, requiring ambulance and hospital service, disinfection, and gratuitous vaccination. It has undertaken to see that our citizens are supplied with pure milk by the arrest and punishment of persons offering for sale an impure article; it is also charged with the duty of supervising the plans for all tenement and apartment houses, the registration of plumbers, the establishing of rules for, and the inspection of all new plumbing work, a duty second to none other in importance.

The President of our Board of Health is a gentleman well known as a man of science and ability, who is just completing his second term of an office which he has filled to the eminent satisfaction of the public. His colleagues are the President of the Police Department and two physicians of eminence, one of whom is Health Officer of the Port. For efficiency and intelligence our Board has received repeated acknowledgments from sanitarians at home and abroad; and as specimens of its good work we can point with pride to its control of small-pox, and to its more recent success in arresting a threatened epidemic of typhus fever in the spring of 1881, and again in the following year. Its counsels are often sought by health authorities of other cities, who have copied the general features of its organization and work with success.

The duty of caring for the public health is too important and responsible to be influenced by any political considerations. We cannot afford to take any backward steps. Such will certainly be the case if the proposed charter passes as it stands.

GOVERNOR BUTLER AND THE CHARGES OF MISMANAGEMENT OF THE TEWKSBURY ASYLUM.

ON Tuesday last the Committee on Charitable Institutions began its investigations into the charges of mismanagement of the Tewksbury Almshouse, made by Governor Butler in his inaugural message. The Governor has conducted the investigation personally in his well-known style. The investigation is interesting to the public, not only from the fact that the whole subject of the care of the sick and insane poor and of foundlings is brought forward, but also grave charges are made against the management in relation to the disposal of the pauper dead. This latter point is the one on which Governor Butler lays the greatest stress, and on which the witnesses examined have been most closely questioned.

The principal witness on this subject was a physician, a graduate of the Harvard Medical School in 1873, who swore that he dissected at least fifty or sixty babies a year, besides adults. At that time there were two hundred or three hundred students in the school. It may be that the witness was a more zealous anatomist than others in the school, and that he was able to obtain more babies for dissection than others, though he states that several of his classmates obtained an equal number. Now, it has been shown that the average number of deaths of infants under one year of age in this almshouse during the years 1870-73 was forty-seven. Yet he says that he was "told" that the babies all came from Tewksbury.

The examination of other witnesses brought out the fact that bodies were removed from Tewksbury at night in a covered wagon, a very proper method of proceeding, one would think, and up to the present time it has not been shown that any of these bodies were removed and sent to the medical schools contrary to the provisions of the Anatomy Act.

Other charges are made against the managers of the institution, such as neglect of sick and insane inmates, misappropriation of supplies, etc. Whatever the examination may show later, up to this time it has only proved the desire of the Governor to make political capital at the expense of dragging the secrets of the dissecting-room before the public, which is to the last degree indecent and unnecessary.

Koch's REPLY TO HIS CRITICS.

IN a recent communication to the *Deutsche Medicinische Wochenschrift*, Dr. Robert Koch has published an elaborate review of the various criticisms made against his experiments and conclusions regarding the tubercle bacillus.

He premises by saying that investigators have somewhat lost sight of the chief point which he made, viz.: that tuberculosis must be a parasitic infection because he caused it by inoculating the isolated parasites. He refers to the fact that in nearly all instances the bacilli have been found in phthisical patients and in no others. The few failures he attributes to lack of diligence in examination, the bacilli being sometimes few in number, or to want of skill in microscopic technique.

He then takes up the various criticisms and answers them in detail. We observe that it is only among Americans and Germans that he finds persons who have ventured to oppose his views.

Dr. Ephraim Cutter's opinion that Koch's discovery is not new, and that his bacilli are only the "babies" of Salisbury's *mycoderma aceti* is stated without comment.

Dr. Rollin R. Gregg "appears to have considered," says Koch, "that microscopical investigations would be superfluous for the establishment of his views."

Schmidt is commended for his honest desire to find the bacillus, but is advised that it would have been better if he had had the patience to wait till he had obtained good colors and learnt how to use them, before announcing fat-crystals as bacilli.

Dr. Formad, of Philadelphia, is complimented as a more skilful microscopist. Still he has not, Koch thinks, yet learned to distinguish the bacilli of tuberculosis. He is further accused of being a prejudiced observer, having certain preconceived views regarding the lymphatic system of scrofulous animals. Finally, Koch states that Dr. Formad cannot give authoritative evidence upon the subject of tuberculosis until he has learnt to find the bacilli with certainty, and until he has made himself familiar with the literature of tuberculous inoculations, especially of those of Cohnheim and Salomonsen, Hänsell, Schuchardt, Baumgarten, and Damsch, and until he has become sufficiently expert in experimental technique not to let his animals inoculated with wood, glass, and metal, die of tuberculosis.

Turning then to his German critics, Koch says: "If one thinks that German medicine cannot bring forth such blossoms of tubercle-bacilli literature as America, he is mistaken."

Beneke, who discovered, as he thought, bacilli in the ethereal extracts of the blood of healthy men, really found, says Koch, fat-crystals, like Schmidt's.

Crämer announced that by using Ehrlich's coloring method he had found bacilli in the stools of twenty healthy persons. Koch cites contrary results obtained by Gaffky and states that Crämer's bacilli were not identified with those of tuberculosis.

Balogh found in the Berlin mud, after a rain, bacilli like those of tuberculosis. Koch, from examinations of his own, contradicts Balogh, and denies any value to the inoculation experiments made by that investigator.

Schottelius produced anatomical tuberculosis in dogs by causing them to inhale masses of finely pulverized non-tuberculous matter. Koch states that the anatomical appearance is not the criterion of what is tuberculous matter, and that Schottelius' experiments are completely contradicted by those of Bertheau and Wigart. Koch also argues against the view of Schottelius that bovine and human tuberculosis are not identical.

Dettweiler has tried to show that the bacilli of tuberculosis are accompaniments, not causes of phthisis, because their inoculation is always followed by acute milary tuberculosis, not by the pulmonary phthisis seen in man. Koch thinks he would change this view if he had a better knowledge of the pathology of tuberculosis.

Koch finally reviews Spina's recently published criticism, which has excited much attention, because this critic alone had repeated Koch's cultivations and inoculations.

Koch says that "Spina's microscopic technique is almost entirely different from that employed to-day in the study of bacteria." He speaks of Spina's "mistreatment of the bacilli with coloring methods," compares his

work with that of Schmidt, and believes that all the new conclusions of Spina as regards staining are valueless. Spina's cultivation and inoculation experiments are also characterized as imperfect and ill-conducted, and as being but "characatures" of Koch.

Koch's reply shows how exacting and careful all experimenters must be in order to test fairly the problem he has claimed to solve. It shows also Koch's great confidence in the fact that he alone so far has carefully, accurately, and impartially studied and settled the question.

MORTALITY IN THE UNITED STATES.

THE statistics published in the Compendium of the Tenth Census show a total mortality, during the census year, of 756,893 deaths. This gives the low ratio of 15.1 per thousand. Allowing for deficient returns, however, the actual mortality rate is estimated to be about eighteen per thousand. This is a better showing than can be given by any other civilized country, so far as is known. Thus the death-rate for the whole of England, in 1880, was 20.5 per thousand; for Scotland, in 1878, it was 21.3 per thousand. In other European countries the death-rate is about as follows:

Denmark.....	20.2 per 1,000
France.....	24.2 per 1,000
Prussia.....	27.1 per 1,000
Austria.....	32.2 per 1,000
Italy.....	30.2 per 1,000

The death-rate is found to be considerably higher among the colored race than among the whites. Thus in the Southern States it is over 17.28 for the former, and about 14.04 for the latter. This excess of mortality is attributed to the great number of deaths among the infants of the colored population. As we showed some time ago, however, the negro race is so prolific that its actual increase in numbers has been greater, proportionately, than that of the whites, and this despite the fact that their numbers receive no accessions from outside.

While the males in the United States number nearly nine hundred thousand (872,857) more than the females, the death-rate is 15.35 per thousand for the former, and 14.81 for the latter. This corresponds with the law that more male infants are born and more die than females.

The relation of age to mortality is shown in the following table:

	Male.	Female.
Total number of deaths.....	390,644	363,874
Ratio of deaths under 1 year to total deaths....	24.803	21.538
Ratio of deaths under 5 years to total deaths...	41.951	38.185
	Male and female.	
Ratio of deaths between 5 and 15 years to total deaths....	8.757	
Ratio of deaths between 15 and 60 years to total deaths....	29.966	
Ratio of deaths over 60 years.....	17.24	

These figures, if they represent the truth, show a very marked excess of infant mortality, and one which has not, we believe, so far been alluded to in the numerous comments upon the census. One-fourth of all the male deaths occur among children under one year of age. This is a higher rate than exists even in the city of London, where, in 1871, it was only 20.8 per cent. for both sexes. In 1862 Dr. Letheby found that this same death-rate (20 per

cent.) existed, and commented upon it as being very high. The death-rate among children under five years of age is also about the same as that for London twenty years ago, and is certainly a high one. It must be admitted, therefore, that our infant mortality-rate is proportionately very high indeed.

The causes of death could be obtained in only 733,840 cases. They are classified as follows:

		Per cent.■
Measles.....	8,772	
Scarlet fever.....	16,416	
Diphtheria.....	38,398	5.23
Whooping-cough.....	12,202	
Enteric fever.....	22,902	3.121
Diarrhœal diseases.....	65,565	
Consumption.....	91,551	12.475
Diseases of nervous system.....	83,670	
Diseases of respiratory system.....	107,904	
Diseases of digestive system.....	34,094	
Malarial diseases.....	20,261	2.761
Accidents and injuries.....	35,932	

Diphtheria, enteric fever, and malarial fever are all found to be more prevalent in small towns and rural districts than in large cities. For diphtheria and typhoid the difference in favor of the cities is between five and ten per thousand on all deaths reported. Consumption also is less prevalent in the large cities of the North Atlantic and lake regions than in the rural districts. We note in this connection, that Colorado, with a population of 194,327, has a mortality from phthisis of 420, and from other respiratory diseases of 1,012, the total number of deaths from all causes being 4,094.

In Florida, on the other hand, with a population of 269,493, the deaths from phthisis were 263, and from other respiratory diseases 346, the total deaths from all causes being 3,150. This apparently gives a much more favorable showing for Florida as a health resort.

PENSACOLA'S BOARD OF HEALTH.—It appears from the following presentment of the grand jury that the Board of Health of Pensacola, Fla., is held responsible for the yellow fever epidemic which occurred there in September and October last: "We find the Board of Health of this county have been grossly negligent of their duties, in that they did not take proper sanitary precautions previous to the introduction of yellow fever into Pensacola in 1882, and in the fact of their having employed an inexperienced and inefficient physician at the quarantine station, and in that after the yellow fever had made its appearance here they failed to take the proper measures for stamping it out, and that they suppressed the information, misleading, not only the people of our city and county, but of neighboring cities and States, causing distrust for the future; and from these causes we consider them responsible for the loss of many valuable lives, and of incalculable injury to the business interests of the city. We, therefore, recommend to the Governor that he shall appoint a new Board of Health, . . . and we would suggest such a revision of the quarantine laws as that it may be made absolutely efficient, either by land or water." The members of the Board have since resigned.

News of the Week.

THE NEW YORK NEUROLOGICAL SOCIETY held its annual meeting April 3d. The following officers were elected: Dr. Wm. J. Morton, *President*; Dr. L. Weber, *First Vice-President*; Dr. Farrington, *Second Vice-President*; Dr. M. J. Roberts, *Secretary*; Dr. M. Putnam-Jacobi, *Corresponding Secretary*; Dr. E. C. Harwood, *Treasurer*.

GIFT FOR A VERMONT HOSPITAL.—Mr. Chauncey Warner has given some property for the establishment of a free hospital in St. Albans, Vt. An organization for the building and managing of the institution has been effected.

A GRAVE ROBBERY AT CAMILLUS, N. Y.—A body was recently stolen from the cemetery at Camillus, N. Y., and taken to Syracuse, where it was left in the dissecting-room of the Syracuse Medical College. The officers found it in this place. It had not been purchased by the College, as the vender was unknown.

NEWPORT AS A RESORT FOR CONSUMPTIVES.—A controversy is going on in the *Boston Medical and Surgical Journal* between Dr. J. H. Tyndale and Dr. H. R. Storer, regarding the climate of Newport. The former gentleman denies the claims of Dr. Storer that Newport is a favorable climate for consumptives.

BIRTHS AND DEATHS IN NEW JERSEY.—According to the statistical report of the State Board of Health there were 25,942 deaths in New Jersey in 1882, an increase of 5,000 over the previous year. There were 8,837 marriages and 23,108 births.

SYPHILIS IN THE MONKEY.—M. Martineau reports progress as regards the syphilitic lesions in the monkey inoculated by him. On the fifteenth day mucous patches appeared, and the monkey showed signs of constitutional disturbance. The question whether lower animals can be affected with syphilis, which seems likely to be settled by M. Martineau, is not one of scientific interest alone. The pathology and treatment of the disease can be greatly helped by a study of it upon such animals.

THE MEDICAL DEPARTMENT OF THE STATE UNIVERSITY OF IOWA will insist in future that all applicants for admission must pass a preliminary examination in the English branches.

SCIENCE.—This is the title of a new journal published weekly at Cambridge, Mass., by Moses King, and edited by S. H. Scudder. It is intended to occupy such a position as is held by *Nature* in England. The first numbers have been excellent, and the journal promises to be a help and credit to American science.

We venture to criticise, however, the plan of introducing pictures and biographies of living American scientists. This is a catch-penny practice not countenanced or desired by earnest scientific workers.

HOSPITAL ABUSES.—“The Hospital Abuses of London” is the subject of a very elaborate and caustic paper by Mr. Henry C. Burdett, in the current number of the *Nineteenth Century*.

Mr. Burdett complains of the very large number of small, semi-private, special hospitals. These are gene-

rally run in the interests of a single doctor, who superintends it and whom it advertises. Benevolent people are imposed upon; the profession and the larger and legitimate hospitals are injured.

The same abuses are appearing in the large cities of this country. It behooves the profession and the public to be on the watch against these semi-private, special hospitals.

THE TREATMENT OF HEART-COMPLICATIONS IN RHEUMATISM.—Dr. Sansom's lectures on heart diseases before the Medical Society of London have aroused renewed discussion as to the therapeutics of cardiac complications in acute rheumatism. Dr. MacLagan has again brought forward his views as to the value of the salicyl compounds, and especially salicin. He urges that small doses are ineffectual, but that we should employ large doses and at frequent intervals, say twenty to forty grains every hour for six hours, or until relief from pain is experienced. Dr. MacLagan thinks we may, by the early and free use of salicin, *prevent* valvular inflammation. Dr. Sansom, while endorsing much that Dr. MacLagan says, is not so sanguine as to the preventive action of salicin.

SANITARY INSPECTION OF SCHOOLS IN OHIO.—An important bill for the sanitary inspection of all schools in Ohio has recently passed the Legislature of that State. The following are some of its main provisions:

The board of health may take measures and supply agents, and afford inducements and facilities for gratuitous vaccination and disinfection, may afford medical relief to and among the poor of the corporation, as in its opinion the protection of the public health may require; and during the prevalence of any epidemic, may provide temporary hospitals for such purposes; and the said board is hereby required to inspect semi-annually, and oftener, if in the judgment of the board it shall be deemed necessary, the sanitary condition of all schools and school buildings within the limits of the corporation.

A NEW CLINICAL JOURNAL, the *Zeitschrift für Klinische Medicine*, is to be edited by four prominent German professors, representing the Berlin and Vienna Schools. These are Frerichs and Leyden, Bamberger and Nothnagel. The journal is to be devoted to the cultivation of internal medicine.

THE ALLEGED POTENCY OF IODOFORM IN LARYNGEAL ULCERS is being questioned by some eminent Vienna specialists. Professor Schrötter, who claims to have seen “many thousands of cases of tuberculous ulceration of the larynx,” states that he never saw iodoform do any good. The Vienna Medical Society has appointed a committee to report upon the subject.

THE CHÂTEAUVILLARD PRIZE of the Paris Faculty of Medicine has been divided between Dr. Giraud Teulon for a work entitled “Vision and its Anomalies,” and Dr. Cadial, for a “Treatise on General Anatomy.”

PROLONGING THE COURSE OF MEDICAL STUDY IN BAVARIA.—The Munich Medical Society has presented a petition to the Bavarian Government asking that the course of medical studies be prolonged from four years to five. The petition is widely signed and appears to be favorably received.

THE ALKALINE TANNATES, *e.g.*, the tannate of sodium, is said by Prof. Pribram to be a very efficient diuretic, and useful in dropsies from nephritis.

POP-CORN AS A REMEDY FOR THE VOMITING OF PREGNANCY is recommended by Dr. T. C. Wallace, of Cambridge, N. Y. The writer states (*Philadelphia Medical and Surgical Reporter*) that for the past four years he had always found it beneficial, and generally a sufficient remedy.

THE STORY OF A STOLEN DIPLOMA.—A student in the Medical School of Maine a year ago was plucked at his final examination. His diploma, however, had been made out and he managed to get possession of it. The party then came to New York and put out his sign. It was discovered that things were not as they should be, and a requisition for the young doctor was served on the Governor of New York. It was not successful, however, and he continued to practise. A short time ago he returned to Bowdoin, thinking that matters were settled. He was arrested on the charge of larceny and placed under \$100 bonds (which raises the query whether this is the legal market value of a diploma). He declined to contend and was ordered to appear later and receive sentence.

DR. WILLIAM SALISBURY HEADLEY died at his residence, in this city, on March 31st. Dr. Headley was born at Walton, N. Y. He was educated at Union College, and was a graduate of the College of Physicians and Surgeons of this city. He practised medicine in Syracuse for a time, but impaired health compelled him to give up his profession. For the past thirteen years he had been Assistant Appraiser in the Department of Drugs in the Public Stores in this city.

DEATH OF DR. M. A. WILCOX.—The death of Dr. M. A. Wilcox, of Halifax County, N. C., one of the oldest physicians in the State, is announced.

SCARLET FEVER AND CEREBRO-SPINAL MENINGITIS IN HORSES.—A writer in *The New York Times* comments on the claim of Dr. J. W. Stickler to have discovered a preventive of scarlet fever in the equine virus. He adds:

"I have long known that scarlet fever exists among horses, and that it has been recognized, especially by French veterinary surgeons, but could obtain no information about it in New York, although I was well satisfied that it lurked among one of the forms of so-called 'pink-eye,' and I have several years ago called attention to this fact. It is well known, also, that the great epidemic of cerebro-spinal meningitis among horses, in 1871, was followed by the greatest outbreak of that disease among our citizens in 1872. There is some well-established connection between the two. I have long thought that scarlet fever and cerebro-spinal meningitis were carried by grooms and hostlers to their own homes, and perhaps to those of their masters and patrons, but could not positively prove the facts, because so much concealment and prevarication is always covered around such matters, arising from ignorance and surprise at such notions, more perhaps than from deceit."

SWIMMING SCHOOLS AND PUBLIC BATHS are to be established in Paris. A nominal charge for their use will be made.

CONVICTION FOR THE SALE OF ADULTERATED SULPHUR.—A druggist in this city was lately convicted and fined \$10, at the suit of the State Board of Health, for selling as precipitated sulphur a mixture of sulphur with thirty per cent. of plaster-of-Paris.

THE ASTLEY COOPER PRIZE.—The next triennial prize, founded by the late Sir Astley Cooper, will be awarded for the best essay or treatise "On Diseases and Injuries of the Nerves and their Surgical Treatment; together with the Operations Performed upon Nerve-Trunks in the Treatment of Various Diseases, and Descriptions of the Changes which ensue in the Structures as well as in the Nerves Themselves from the Operations." The money value of the prize is £300. It is open to the whole world. Essays must be sent to Guy's Hospital before January 1, 1886.

THE CULTIVATION OF TUBERCULAR BACILLI.—It is somewhat noteworthy that although a year has passed since Koch announced his discovery of the bacilli of tuberculosis no one has yet repeated his experiments. The explanation is, no doubt, due to the fact that the experiments are difficult and require a large outlay of time and money, besides much technical skill. We learn now, however, that Professor Feltz, of Nancy, has been attempting to cultivate the bacilli, following strictly Koch's descriptions. He announced recently that all these attempts had proved utter failures, although he exactly followed the directions given by Dr. Koch for this purpose in his original paper. "In presence of my failures," he says, "I could not be sufficiently thankful if I were furnished with the necessary information to enable me to avoid this kind of misadventure: for I would not cast a doubt, from the facts only which I have just mentioned, upon those which Dr. Koch has so positively affirmed."

SMALL-POX IN NASHVILLE has become very prevalent. About forty-eight cases were reported in two weeks.

DR. R. S. HUIDEKOPER has been elected Professor of Veterinary Anatomy and Pathology in the proposed Veterinary Department of the University of Pennsylvania.

THE NEW YORK INFANT ASYLUM—A CORRECTION.—In THE RECORD of last week Drs. Græme M. Hammond, William M. Polk, Cyrus Edson, Lewis H. Sayre, and T. E. Satterthwaite are reported as members of the Medical Board of this asylum. We are informed by these gentlemen that this is an error, as they hold no medical positions in this institution.

EXPERIMENTAL INVESTIGATIONS INTO THE NATURE OF CONTAGIOUS DISEASES IN ANIMALS.—We are glad to announce that the Government has at last undertaken to make some experimental investigations into the nature of infectious diseases in animals and the value of protective vaccinations. The Department of Agriculture has leased a piece of ground in the suburbs of Washington to be used as an experimental farm and hospital. The grounds are being put in order and buildings erected thereon. Dr. D. E. Salmon, who has for several years been employed by the Department in the investigation of diseases of cattle, swine, and poultry, will arrive in Washington about May 1st to take charge of the work. Dr. Salmon will bring with him a number of cattle and

sheep, and the experiments will begin soon after his arrival. The Pasteur system of inoculation will be adopted. The investigations now to be made will be on a much larger scale than any heretofore attempted by the department, and will be conducted with the view of ascertaining the origin, causes, and nature of the Texas cattle fever, pleuro-pneumonia, and hog and chicken cholera, together with means of preventing and curing these diseases.

QUARANTINE AT NEW ORLEANS.—Governor McEnery has issued a proclamation establishing a quarantine of not less than ten days against vessels, crews, passengers, and cargoes from the Mexican ports of Matamoros, Tampico, Tuxpan, Vera Cruz, and Minatitlan; Porto Rico and Jamaica, and the Brazilian ports of Rio de Janeiro, Bahia, and Pernambuco; other West India Islands and ports along the isthmus and the coast of South America to Brazil; the Islands of Barbadoes, St. Thomas, Martinique, Guadeloupe, and Trinidad, and the ports of Colon, Cartagena, Savanilla, Baranquilla, Laguayra, Georgetown, and Cayenne. The quarantine will go into effect May 1. It is unusually severe, and practically prevents intercourse with the specified points.

DR. NATHANIEL LOW died at Dover, N. H., April 3d, aged ninety. He was graduated at Dartmouth in 1869, and held numerous offices of trust in New Hampshire and Maine.

DR. JOSEPH H. BAILEY, United States Army, died at his residence, at Kent Cliff, N. Y., April 1st, in his eightieth year. Dr. Bailey entered the United States Army in 1834, as Assistant Surgeon. He was promoted to the rank of Captain in 1839. In 1862 he was retired from the service through a disability obtained in the line of duty.

PROFESSOR LASÈQUE, the eminent alienist, died recently, in the sixty-seventh year of his age, after a long illness, deeply regretted by all who knew him. He took his degree in 1846, and became successively "Chef de Clinique," Hospital Physician, Agrégé, and Professor of the Faculty, and it was only in 1876 he was elected member of the Academy of Medicine. He was nominated Chevalier of the Legion of Honor in 1850, for his zeal during the cholera epidemic of 1849, and was promoted to officer in 1871, in recognition of his distinguished services during the siege of Paris. But it was as a medical jurist in mental cases that he particularly distinguished himself. Dr. Lasèque's literary productions were confined principally to medico-psychological subjects, in which he eminently excelled, though his contributions to the "Archives Générales de Médecine," of which he was the principal editor, bore testimony to the profoundness of his knowledge of general medicine. He was for some years clinical professor at the Hôpital la Pitié, where his lectures were well attended, and he displayed great skill in diagnosis. He also proved himself a therapist of a high order, in which branch he equalled, if not surpassed, his former master and friend, the much-lamented Trousseau.

EXHIBITION OF INSECTS IN PARIS.—An exhibition of great interest to the agricultural and industrial world is to be held in Paris in July next. The exhibition will

comprise different sections of useful and destructive insects, showing their products in a raw state, the apparatus and instruments employed in their transformation for the various purposes of arts and manufactures, as well as the means adapted for the destruction of injurious insects. During the exhibition an insectological and an agricultural congress will also be held. The insectological congress will treat of the nature and importance of the injury caused by insects, the means employed for their destruction, and those proposed to favor the development of birds and reptiles which contribute to their destruction. The phylloxera and its habits will be particularly treated of, and sericulture will form a very important section of the exhibition. The agricultural congress will study the creation of artificial hives and the most practical means for increasing the production of honey. The exhibition, which is to be organized under the patronage of the Minister of Agriculture, will take place at the Palais de l'Industrie.

GAV-LUSSAC, the distinguished chemist and son of the illustrious "savant" of the same name, died recently in Paris at the age of sixty-three years. His works on chemistry are well known, but those on metallurgy were particularly appreciated.

A NEW DOLMEN has just been discovered at St. Pierre Quiberon in Brittany. The dolmen contained four skeletons in a perfect state of preservation, and in one corner was found some twelve or fifteen skulls. Among the bones were also found two hatchets in silex, a long pin in bronze, and some fragments of pottery. M. Gaillard, of Plouharnel, who was charged with the restoration and the preservation of Celtic monuments, immediately resorted to the locality and had a photograph of the dolmen and the skeletons taken. Judging from the position in which the latter were found, one would conclude that they were thrown there anyhow. This discovery is considered very interesting, and M. Gaillard states that it will throw some new light on the question of Celtic monuments. Up till now skeletons or loose bones had not been found near dolmens or menhirs. The skeletons of Quiberon would therefore appear to justify the hypothesis that the stones there found formed part of the monuments indicating the places of sepulture.

THE ANNUAL COMMENCEMENT OF THE COLUMBIA VETERINARY COLLEGE AND SCHOOL OF COMPARATIVE MEDICINE was held at Chickering Hall, March 29th. Twenty-five students were graduated, this being one of the largest classes ever graduated in the city. The valedictory was delivered by Dr. Henry C. Slee, of Brooklyn. The degrees were conferred by Dr. Alexander Hadden, President of the College. Junior certificates were awarded by the Dean, Dr. E. S. Bates, to a large class. The prizes, which were numerous, were awarded by Professor Hubbard W. Mitchell. Judge Rufus B. Cowing delivered the address to the graduates. Hon. Andrew L. Souland, delivered the concluding address. The audience was a very large one.

THE NEW MEDICAL SCHOOL IN BOSTON AND "SARCOGNOMY."—On Monday last, the College of Therapeutics, being the "medical department of the American University," was formally opened. The medical department of this great institution, by the way, is the

only department to be opened at present. The principal address was made by Dr. J. R. Buchanan, the president. He states that "the college will have the scientific basis of Sarcognomy, a revelation of the philosophy of the human constitution, explaining the relations of soul, brain, and body." It is, perhaps, unnecessary to remark that the "University" hopes to issue diplomas, for a consideration, to a large number of graduates.

SUICIDE OF A PHYSICIAN.—Dr. John W. Ferguson, of Charleston, S. C., was found dead near Savannah, April 1st. He is supposed to have committed suicide.

Reviews and Notices.

MANUAL OF GYNECOLOGY. By D. BERRY HART, M.D., F.R.C.P.E., Lecturer on Midwifery and Diseases of Women, School of Medicine, Edinburgh, etc., and A. H. BARBOUR, M.A., M.B., etc. Vols. I. and II. With Plates and Woodcuts. New York: Wm. Wood & Co. 1883.

It was a wise choice on the part of the publishers to select Hart and Barbour's "Gynecology" for the opening volumes of their Library for 1883. The treatise before us is different from all other works on diseases of women with which we are acquainted, and for the general practitioner, if not for the specialist, this new manual is in some respects superior to them. In the first place, it does not reflect the bias of a single mind, nor does it represent the system of an exclusive school. It is not a distinctively English, American, French, or German gynecology, and yet it is somewhat of all of these. It might be supposed from the international character just alluded to that it was confusing on account of the multiplicity of counsel offered; but the judicious eclecticism of the authors has enabled them, in most instances, to steer clear of such a fault.

We cannot attempt to analyze seriatim the different sections of the work, but we may give some idea of the scope of the manual by a cursory examination of the plan of arrangement of the subject matter. The entire treatise is divided into two parts, the first dealing with anatomy, physiology, and methods of gynecological examination, the second being reserved for the detailed description of diseases of the pelvic organs. We have no hesitation in stating our preference for the first part. Here Dr. Hart's personal studies have enabled him to present a well-worn subject in an original and attractive shape. The style, however, is often marred by poor diction, the result, in many instances, of forced brevity, while yet the desire to be explicit, is evident throughout. In a second edition these faults will doubtless be largely remedied.

Part Second, forming the main bulk of the manual, may be called a well-illustrated and lucid epitome of modern gynecology. The different diseases of women are one by one discussed, generally in a satisfactory manner. We are pleased to note the absence of excessive enthusiasm about favorite methods of treatment or the broad enunciation of pet theories of etiology. The authors are fond of giving facts, and it is to be hoped that this fondness may prove contagious. All the subjects are not evenly dealt with; but perhaps that is excusable, being an inherent difficulty of first editions. There is no doubt in our mind that Hart and Barbour's "Gynecology" will soon be one of our most popular manuals. The mechanical execution of the volumes is excellent. What with good paper, large, bold type, clear woodcuts, and some really satisfactory plates, the publishers may be complimented upon having turned out a valuable work in a proper and becoming dress.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN. By JAMES NEVINS HYDE, A.M., M.D., Professor of Skin and Venereal Diseases, Rush Medical College, Chicago, etc. Philadelphia: H. C. Lea's Son & Co. 1883.

In this treatise of 560 pages Dr. Hyde has presented us with the main features of dermatology as they appear to-day. No claim as regards completeness can be made for the present manual, but in a clear, concise, and practical way the different diseases of the skin are presented in their various aspects of etiology, symptomatology, diagnosis, prognosis, and treatment. For the student and practitioner the book might have been made more valuable still by discarding altogether the more or less artificial and arbitrary subdivisions and varieties of the commoner dermatoses. The dermatologist proper, on the other hand, will probably be inclined to take the author to task for too much condensation and simplification; but as the book was written for the former class, their needs alone should be consulted. On the whole, the work is a commendable one, and will not fail to win the appreciation that it well deserves.

A TEXT-BOOK OF PATHOLOGICAL ANATOMY AND PATHOGENESIS. By ERNST ZIEGLER, Professor of Pathological Anatomy in the University of Tübingen. Translated and edited for English Students by DONALD MACALISTER, M.A., M.B., M.R.C.P. Part I. General Pathological Anatomy. London: Macmillan & Co. 1883.

DR. ZIEGLER's treatise on pathology has quickly achieved a merited popularity in Germany. It is now made accessible to the English student, and will, without doubt, be found by him a welcome guide-book in this department of medicine. The great merit of the present work lies in its elementary simplicity, in its clearness, and in its positiveness. In many existing manuals the reader is confronted by the simple narration of the conflicting views of different observers. And thus the task of gleaning the author's personal convictions often becomes a sorely perplexing one. Not so with Ziegler's manual. He has carefully filtered contending views through the media of a critical mind and extensive personal investigation. And he presents the result as a clear solution of existing knowledge on pathology. That there needs must be a tinge of individuality about a work thus prepared goes without saying. But we have no reason to regret this. It rather makes the book a more even and pleasant one to read, and in no way detracts from its usefulness.

The work is divided into seven sections, and we must content ourselves with simply mentioning the subjects described, as space forbids our examining each one in detail. Section one deals with the malformations, and though short is satisfactory. The second section is devoted to a consideration of anomalies in the distribution of the blood and of the lymph. Retrogressive disturbance of nutrition are next discussed in a very complete way. Then the progressive or formative disturbances of nutrition are examined. The fifth section is an interesting and important essay on inflammation and inflammatory growths. Section six is devoted to an excellent exposé of the intricate subject of tumors. The seventh and last section deals with parasites, and we may conclude by saying that we know of no student's text-book which presents this branch of pathology in so perfect and yet elementary a manner.

We must also congratulate the translator and editor on the good judgment which he has shown in making some needful alterations and additions. We hope soon to see the work completed.

FLUID EXTRACT OF COCA is said to cause anæsthesia of the pharynx when brushed upon the mucous membrane.

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 2, 1883.

JAMES B. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

DR. ROBERT F. WEIR related the history of a case of

HIP-JOINT AMPUTATION, IN WHICH DAVY'S RECTAL ROD WAS SUCCESSFULLY USED.

The patient, a boy seven years of age, had received, in the autumn of 1881, a severe fall, striking upon the right knee. One month later a swelling appeared in this region, which continued to grow, with some pain and some depreciation of general health. Nearly a year later the boy was admitted to the New York Hospital. At that time the tumor had grown so as to involve the thigh-bone, and to reach from the knee to within an inch of the trochanter. Amputation at the hip-joint was decided upon, but the pathological conditions made it necessary to give up the idea of attempting the most rapid method of operating, *i.e.*, by anterior and posterior flaps. Instead of this the slower procedure of making a circular division of the muscles a little lower down, then gradually working up to the joint, was determined upon.

The control of the hemorrhage in such cases could be made in three ways: either by an abdominal tourniquet, by the use of Trendelenberg's transfixing rod (which is passed for the anterior incision in front of the bone, and then a rubber tube is wound half round the limb and caught in a figure of 8 turned over the projecting ends of the rod, in this way compressing the vessels, after which the flap is made, vessels secured, and the same procedure resorted to for the formation of a posterior flap), or by the employment of a rectal rod. This latter method was suggested by Mr. Richard Davy in 1878, and has since been resorted to some twenty-two times, and with very good results. The rod, about two feet long and the size of one's finger, is passed up the rectum about eight inches, until it reaches the common iliac artery, which it presses against the subjacent structures. In this case the rod (a syringe of oil having been first thrown into the bowel) was very readily passed up the rectum on the right side, and rested nearly parallel to the spine; the outer end was then tilted up and the artery easily controlled. There was a little slip once during the operation, and a spurt of blood, but this was promptly stopped. The vessels were secured by bull-dog forceps and ligatured. The total amount of blood lost was only two and a half ounces. The wound was dressed with bichloride of mercury dressing, and left open in its lower half. The patient recovered very satisfactorily and was shown to the Society. The tumor was a round-celled sarcoma of a very juicy nature and likely to return. It had its origin in the bone, however, and some authorities think that in such cases a return is less probable.

There is one point in relation to the use of the rod which is of interest in other than a surgical point of view. In the region compressed by this rod the

URETER

is also found, which tube we sometimes wish to compress in order to determine the comparative condition of the two kidneys. Dr. Sands suggested some time ago, in trying to acquire a knowledge of the condition of a single kidney, the passage of the hand into the rectum and compression of the ureter thereby. The speaker thought that, by the use of the rectal rod, this might be better done, and for the accomplishment of this idea one end of the rod had been broadened and flattened.

In seven of the cases in which the rectal rod had been used for the control of hemorrhage in hip-joint amputations, there had been only a total of seven ounces of

blood lost. One accident only had taken place in its use, which occurred in the experience of Mr. Davy himself. In this case, narrated in the *Medical News* of July 8, 1881, twenty-four hours after amputation at the hip-joint, peritonitis set in, due to perforation by the rod, and the patient died. In this case, however, Mr. Davy¹ had been experimenting with a little different instrument. Whatever risk, and it is probably slight, is connected with its employment is confined to the control of the right iliac artery.

With reference to the amputations at the hip-joint in general, by common consent surgeons use the circular method adopted by the speaker, if it is practicable, since the risk is less. It is even suggested by F. Jourdan that one should cut low down, and dissect the bone out of its bed where possible, so as to leave a greater length of soft parts. The mortality is thus diminished, and the stump furnished is a good one.

In the discussion which ensued DR. GEORGE F. SHRADY said that he had seen the operation in question, and was much pleased at the readiness with which hemorrhage was controlled. Dr. Shradly remarked that in Davy's fatal case the right iliac artery was compressed. It seemed to him that there was an anatomical reason why the rectum, which was situated to the left, should suffer from injury under such circumstances.

DR. A. H. SMITH said that when a student, and attending one of Dr. Carnochan's clinics, the idea suggested by Dr. Weir had occurred to him, *viz.*, that it would be better to make the section lower down and dissect out the bone from its bed.

DR. WEIR said, in response to a question, that there was no difficulty in his case in finding the artery and compressing it. The compression did not increase arterial tension, since it cut off only the circulation of one limb. The rod had this advantage over the abdominal tourniquet, that it did not compress the viscera, and thus, perhaps, interfere with respiration.

DR. POLK asked how long the ureter would have to be compressed in order to collect sufficient urine from the other kidney.

DR. WEIR said that in one case which Dr. Sands tried, the ureter was compressed for fifteen or twenty minutes. During this time he collected about half an ounce of urine. He did not think that pressure for that length of time would do any harm.

DR. POLK had been making some experiments in this direction. He had found that by taking an ordinary sound and giving it a double curve, then introducing it into the female bladder and pressing the urethral curve against the wall of the pelvis, the other part of the sound comes square across the track of the ureter. Then by introducing a finger into the rectum and pressing against the sound, the ureter can be occluded completely. In order to test this, the speaker had made the following

EXPERIMENTS ON THE CADAVER.

He opened the ureter just below the kidney. Then having introduced the sound in the manner described and occluded the ureter, he injected water into its upper open end by means of a syringe. Not a drop of water flowed through the ureter, although he had dilated it to the point almost of bursting. He was unable to detect any special erosion of the mucous membrane in consequence of the pressure made. The experiments were performed on two women and one man. The question was whether the bladder in the living subject would stand this sort of treatment.

DR. WEIR said that the sound left in the bladder for some time does not cause any serious trouble. He was much pleased with Dr. Polk's idea, and did not see why it would not prove practicable.

¹ Mr. Davy, in the *Lancet* of February 17, 1883, speaking of his accident, says that his rod has now been used over forty times, twenty of which were on the right side. Under its use there was 65 per cent. of recoveries after amputation at the hip-joint. In seven deaths the rectum had been carefully examined, and in only one (the above) was there any injury to the intestine found.

DR. SEXTON asked if it would not be possible to catheterize the ureter with a suitable instrument.

DR. HUNTER said that he had seen Dr. Emmet do this once in a female.

DR. POLK thought it quite impracticable ordinarily, even in the female. Schroeder had done it once.

DR. DANA said that the pressure of the urinary secretion was quite exactly known, at least in the higher mammals. The rate of flow of urine normally was about an inch a second. It was influenced by the administration of ether, however. Emmet had asserted that

THE FLOW OF URINE OFTEN CEASES IN ETHER NARCOSIS.

DR. HUNTER said that on the other hand it was sometimes increased in that condition. In one case the urine was ejected almost in a spurt.

DR. POLK read the paper of the evening (see p. 374), which was entitled

THE INFLUENCE OF EXTREME LATERAL CURVATURE OF THE SPINE UPON THE COURSE OF LABOR.

In the discussion Dr. Polk, in response to inquiry, said that the patient had been under treatment for two or three years, but he did not think that any of the trunk-muscles had been weakened thereby.

DR. V. P. GIBNEY said that he thought Dr. Polk's view was correct, and that the observation made was a new and important one. Such cases would be apt to escape the attention of orthopædists, because they are rarely seen by them after twenty years of age. It was a common thing in such cases of curvature to have the abdominal organs compressed down into the pelvic cavity, thus, perhaps, affecting the uterus. Ladies who had had Pott's disease had frequently asked him whether they could get married, and he had generally discouraged them.

The exaggerated form of curvature which Dr. Polk described was not very common. A great many persons have a slight deformity; they get treated for a time, the curvature ceases to increase, and they give up treatment. They go through life with a slight deformity which is not noticed.

DR. HUNTER had attended one case of labor in which the lady was the subject of Pott's disease. The patient had suffered from this trouble for two years, and married while still uncured. She had a normal labor, but the child was very small, weighing only three pounds. The disease was low down at about the fourth lumbar vertebra where there was a very decided prominence. There was no contraction of the pelvic outlet.

DR. GIBNEY thought it important to know when the Pott's disease developed. In cases where the disease came on early, even if it was slight, it often affected the growth, the stature was small, the pelvis also might be small. It was further worthy of note that a patient may have Pott's disease, and often does have it, the symptoms being so slight that years may elapse before the fact is recognized. Then some one is examining for the cause of certain pains considered neuralgic and finds the kyphosis (long since solid), and perhaps an old residual abscess just now coming to the surface.

DR. WEIR said that it seemed a fair inference, since so many women had lateral curvature, that Dr. Polk's case was a very exceptional one. He could recall two cases in which there was very great lateral curvature, and in which there had never been any trouble during labor.

DR. F. P. KINNICUTT read a short paper entitled:

A REPORT OF A CASE SHOWING UNUSUAL SUSCEPTIBILITY TO THE SCARLET-FEVER POISON.

In the discussion DR. C. L. DANA related the case of a medical friend, who before the age of twenty-one had suffered from five attacks of scarlet fever. In each case the symptoms had been well marked. Desquamation took place, and in most of the attacks albuminuria was present.

The Society then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 14, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. T. E. SATTERTHWAITE, from the Committee on Microscopy, made the following report: (1) That the tumor of the rectum presented by Dr. Robert Newman at the stated meeting held February 28, 1883, was a *cylindrical epithelioma*; (2) that the placenta presented by Dr. Tauszky at the same meeting was the seat of *waxy degeneration*; (3) that the specimens of *metritis desiccans* presented by Dr. Garrigues at the stated meeting held January 24, 1883, contained smooth muscular tissue.

Dr. Satterthwaite also presented specimens removed from the body of a dwarf upon whom Dr. Richardson, of Philadelphia, a few years ago, performed

PORRO-MÜLLER'S OPERATION.

The patient died of acute Bright's disease. There was a ventral hernia, one of the results of the operation, but it had been so easily supported by a truss that it had not given the woman marked discomfort. The vagina, the cervix uteri, and surrounding tissues were presented and showed the cervical canal intact and containing mucus. The complete history of the case has already been published by Dr. Richardson in the *American Journal of the Medical Sciences*.

DR. W. P. NORTHRUP presented a specimen of

CONGENITAL CYST OF THE KIDNEY—ABSENCE OF THE URETER.

"A male child, aged four months and one week, died in the New York Foundling Asylum with gastro-intestinal catarrh and broncho-pneumonia. There was also cranio-tabes.

The right kidney was about twice the normal size. It seemed normal; the ureter and bladder were in normal condition. The left kidney was a monolocular cyst. There was entire absence of the ureter. The pelvis seemed to be a part of the common cyst.

Remarks.—Virchow has written an elaborate article on cysts of the kidney. 'In all but two cases both kidneys were affected.' In cases of cystic kidney malformation of the pelvis or ureter or bladder were generally found. The theory he gives is of intra-uterine inflammation from impaction of uric acid in the straight tubes, obstruction, dilatation of tubules, Malpighian capsules, until the whole kidney is involved."

Dr. Northrup also presented a specimen of

CALCULOUS PYELO-NEPHRITIS.

"A female child, aged thirteen months; foundling. First appears on the books of the New York Foundling Asylum, 'Aged one day; condition miserable.' Four days after entrance was put into the care of a wet-nurse out in the city and brought to the Out-door Department from time to time. Three months later is an entry, 'Condition poor; vomiting, purging; sprue.' Nine months later, 'Pale, thin; bowels regular.' One month later, and one month before death, was returned to the hospital very much emaciated. Over both lungs were well-marked signs of consolidation. A week later diarrhoea set in again. From this time the child wasted rapidly, developing no new symptoms and showing none at any time referable to the urinary tract. It died February 6, 1883.

Autopsy.—Body: Emaciated; excoriations about buttocks; moluscum sebaceum on the face. Lungs: Broncho-pneumonia of both in posterior portion of upper and lower lobes. Heart: About two drachms clear serum in pericardium; heart itself normal. Spleen: Normal. Stomach: Moderate congestion and increase of mucus. Small intestine: Inflated, little solid material; mucous membrane thin, pale; mesenteric glands enlarged. Large intestine: Membrane dusky red in linear patches, and increase of mucus; intestine empty. Liver: Closely

adherent to the diaphragm, the abdominal walls, and to the tissues covering the right kidney; hepatic substance shows no gross change. Left kidney: Somewhat enlarged; in its pelvis is a calculus moulded to its cavity and filling it; pelvis not dilated, ureter normal. Right kidney: Enlarged to twice the size of its fellow, tightly adherent to the surrounding tissues, capsule thickened and adherent. On section the whole of the spongy fluctuating mass found perforated with cavities radiating from the pelvis to the periphery, and these cavities are filled with grayish, ropy pus. In the pelvis are three or more calculi, varying in size from a pea to a filbert. Ureter is dilated and filled with ropy pus; its mucous membrane is thickened, granular, and red; its orifice at the bladder is slightly larger than that of the left; no obstruction. Bladder contains pus from the right ureter, but its mucous membrane looks normal.

"On examination the calculi are found to be uric acid. The left kidney shows well-marked parenchymatous inflammation, degenerated epithelium, engorged capillaries, hyaline casts. Right shows all gradations from moderate parenchymatous degeneration, engorgement of capillaries to interstitial hemorrhage, inflammatory infiltration, necrosis, abscess detritus. To summarize, the left kidney shows parenchymatous nephritis with calculus; the right shows calculous pyelo-nephritis or suppurative nephritis; right ureter shows dilatation and inflammation.

"The inflammation obviously arose from the irritation of the calculi. In the right the pyelitis became purulent and extended along the straight tubules until nearly the whole kidney was involved. It also extended down the ureter to the bladder, but did not set up inflammation there.

"*Remarks.*—Civiale, in 5,900 cases, found 45 per cent. of calculi in children. Neussauer gives the following table of frequency of calculi: From three to twelve months, 1.55; from twelve to twenty-four months, 1.55; from two to four years, 27.6; from four to five years, 12.5; from five to seven years, 22.4; from seven to twelve years, 17.7; from twelve to sixteen years, 3.63. The most common calculi are the uric acid, and occur more often in males than females (Gerhardt)."

DR. NORTHRUP also presented a specimen of

ENLARGED BRONCHIAL GLANDS AND FALSE CROUP.

"Male; aged eleven months; New York Foundling Asylum. In November, 1882, the child had broncho-pneumonia. From the urgent symptoms the patient recovered after about three weeks. The emaciation and cough remained persistent. Child very white and pinched. The character of the cough simulated very closely whooping-cough—periodic, spasmodic, severe. Râles heard over both sides of chest.

"Two months later there were diarrhoea and vomiting. Cough continues; child pale and thin. Three months later, a week before death, it was taken again with acute broncho-pneumonia. On the following evening laryngeal dyspnoea developed and the symptoms very urgent and severe. On the following day the dyspnoea became less, and did not again become severe. Breathing continued more or less stridulous until death.

"*Autopsy.*—Body emaciated; both sterno-costal regions depressed; brain normal; larynx normal. Right lung: Adherent by tough, slender, scattered filaments over anterior and lateral surfaces; posterior surface covered with recent fibrin; extensive consolidation of the lower and posterior portion of upper lobes. Left lung: Consolidation of about two-thirds of lower and posterior portion of the upper lobe; recent fibrin over the lower lobe. Bronchial glands all enlarged, soft, dusky, apparently the seat of recent change; one large, cheesy gland, about one inch and three-fourths by one inch, was tightly wedged up into bifurcation of the trachea, compressing both bronchi; the gland lies up behind trachea, is firm, exerts pressure forward upon the trachea, and

upward and forward upon the bronchi, diminishing the calibre of both. Heart normal; liver large and fatty; spleen anæmic, reddish, size normal; kidneys normal. Stomach: Increase of mucus, red in linear patches; empty. Intestines: Mesenteric glands enlarged, dusky; solitary follicles swollen; Peyer's patches not changed; crease of mucus. Large intestine appears normal; contents yellow and tenacious."

Dr. Northrup remarked that the case was interesting, because it illustrated the irritation which may arise from pressure of an enlarged gland upon the bronchi or the vagus nerve. There was a spasmodic cough and a nightly attack of what appeared like false croup.

DR. B. LIVINGSTON said that he had had a similar case, in which there was no history of cough. The enlarged gland was an inch and a half in its vertical and three-fourths of an inch in its antero-posterior diameter, and it seemed to press upon both bronchi and also upon the œsophagus, but there was no difficulty of swallowing. There was no croupy cough, but there was broncho-pneumonia, as seen in Dr. Northrup's specimen.

DR. E. L. PARTRIDGE presented specimens illustrating

PURPURA HEMORRHAGICA,

removed from the body of a child *four* months old. The history of the case was furnished by Dr. Remsen, of the resident staff at the Nursery and Child's Hospital. "The child was born in the hospital, and had always appeared to be healthy. No evidence could be obtained of hereditary tendency to the affection. Early in March the mother directed attention to the child, and on examination small ecchymoses were observed quite thickly scattered over the face, arms, legs, and feet, varying in size from a mere dot to a pin's head. Otherwise the child seemed well. It nursed, and the temperature was 98° F. During the night of March 4th it vomited blood and had epistaxis. Wine of iron and cod-liver oil were ordered.

"March 7th.—Patient growing stupid; does not nurse well; very pale; vomiting has ceased; had a bloody stool.

"March 11th.—The child refuses the breast. No vomiting; has attacks of epistaxis; temperature normal; large hemorrhagic spot upon the hard palate, and many smaller ones upon the tongue. Passes urine in small quantities, and only when wrapped in hot blankets. Last night an ecchymosis appeared on the cutaneous surface of the nasal septum, which broke and gave rise to considerable hemorrhage. Continuous oozing of blood from the mouth. The gums appeared normal. The patient died of exhaustion March 12th.

"The autopsy was made by Dr. Beverley Livingston. The body was well nourished, and here and there were remains of purpura hemorrhagica. The heart showed some very small ecchymotic spots on the pericardium. The cavities contained no clots and the valves were normal. The liver was extremely fatty. Spleen normal. Blood fluid. The stomach showed some submucous hemorrhages, but there was no fluid-like blood in either the stomach or intestines. The right kidney was very pale and the pelvis contained a number of small calculi. The left kidney showed several small hemorrhages under the capsule and also scattered in the substance of the organ. There was some bloody fluid in the supra-renal capsules. There were no calculi in the bladder, and the urine it contained was clear. Dr. Livingston exhibited microscopic slides of the blood, taken post-mortem, which showed chain bacteria in abundance. They had taken the methyl-violet staining, and their presence he regarded as difficult to explain. He did not regard the micro-organisms as the result of decomposition. The number of white blood-corpuscles was materially increased."

DR. NORTHRUP referred to a case of purpura hemorrhagica, occurring in a child, in which, soon after death, the skin became intensely yellow.

Dr. VAN GIESON thought that absence of bloody urine was a point worthy of note.

Dr. GARRISH remarked that the affection usually occurred in the poorly nourished. In all the cases he had seen bloody urine had been passed and hemorrhage from the gums had occurred. In one case, that of a man ninety-two years of age, blood oozed from every part of the body. In two cases occurring in children, six and ten years of age, he had given the fluid extract of ergot, and both patients recovered.

SUBPERIOSTEAL REMOVAL OF THE RADIUS—REPRODUCTION OF THE ENTIRE BONE.

Dr. J. A. WYETH presented a radius removed from the left arm of a boy ten years old, who six weeks before the operation received an injury to the wrist-joint that caused separation of the epiphysis, followed by necrosis. The operation, performed in November, 1882, was a subperiosteal one, and since that time the radius has reproduced itself entirely, and there is free motion at the wrist-joint and about 15° motion, with pronation and supination at the elbow.

FRACTURE OF THE NECK OF THE FEMUR.

Dr. Wyeth also presented the upper part of the femur of a woman who died at the age of sixty-seven years, and who suffered at the age of sixty-two from what was supposed to be fracture of the neck of the thigh-bone. She was under the care of Dr. William Selden, of Norfolk, Va., who gave the history that the patient fell upon a carpeted floor, was unable to rise, was carried home, and when the doctor arrived, he found the characteristic deformity of fracture of the femur high up. Careful measurement showed that there was from three-fourths to one inch shortening. He regarded the case as one of fracture of the neck of the femur, probably within the capsule. He put the patient into bed, kept her quiet, and no other treatment was adopted. The patient so recovered that she was able to walk without a crutch and showed no signs of lameness for several years, although it took a year to recover from the injury.

Dr. Wyeth also presented two

CARTILAGES FROM THE KNEE-JOINT,

removed post-mortem. They were found in the synovial bursa, connected with the knee-joint, lying over the most external tendinous insertion of the semi-membranous muscle. They were found at the bottom of this pouch, close to the side of the bone, but not adherent to it. Dr. Wyeth believed that they developed in the bursa.

Dr. Wyeth also presented the contents of an

OMENTAL FEMORAL HERNIA

removed from the same body, and the specimen was interesting because it demonstrated the fact that an omental hernia can cure itself. The mass had come partly through the femoral canal, had become incarcerated without being strangulated, and had become adherent. It was the third specimen of omental femoral hernia that he had seen.

Dr. Wyeth also presented the fragments of an

ENGLISH GUM CATHETER REMOVED FROM THE BLADDER.

The patient had suffered from a severe accident which involved the spinal cord, but his locomotion was good. He was obliged to use a catheter, and lost the instrument in the urethra, from which locality Dr. Wyeth attempted with several different instruments to extract it, but it slipped on into the bladder before he succeeded. He then removed it by the aid of a lithotrite. There was almost complete anesthesia of the urinary tract, the patient feeling the lithotrite only when quite vigorous pressure was made with the instrument on the floor of the bladder.

Dr. Wyeth also presented several

PHOSPHATIC CALCULI

which he had removed from the bladder by means of Thompson's evacuator, although no stone could be detected by sounding. The patient had marked cystitis. Dr. Wyeth thought it well to resort to this method in similar cases, with the view to determining whether or not calculi were present which could not be touched with the sound.

THE PRESIDENT referred to a case in which he performed the sub-periosteal operation for acute necrosis of the humerus, and the result was reproduction of the entire shaft of the humerus. The results in these cases showed how much the periosteum had to do with production of bone as compared with the epiphyseal cartilages.

Dr. FERGUSON presented a specimen of

ANEURISM OF THE ARCH OF THE AORTA.

"The specimen was from a male, aged forty-five, a native of the United States, and a news-dealer by occupation. He was admitted into the New York Hospital on March 4, 1883. He had been temperate in his habits. Some of his remote relatives had phthisis. He had had a chancre, but secondary and tertiary syphilitic symptoms were not well marked. He gave a history of sun-stroke, rheumatism, and malarial fever, the latter during the months of June and July of last year. The attack was attended by cough, elevation of temperature, and sweating, but no chills. Following this his health was good until last November, when his cough returned, accompanied by pains in his chest. A month later he noticed his voice failing, and he suffered from moderate dyspnoea. Three weeks previous to his admission into the hospital, he began to be troubled with spasmodic attacks of dyspnoea, coming on without any apparent cause, and not accompanied by cough. During that time he had six of these attacks, each more severe than the preceding one, and the last so severe as to occasion fears of a fatal issue. The last occurred immediately after eating, and for the first time he noticed difficulty in swallowing. During the intervals he was almost entirely free from dyspnoea. He gave no history of violence, cardiac, or renal disease.

"On admission, patient was noticed to be indifferently nourished. The face was slightly cyanotic; there was no oedema. His respiration was much embarrassed, inspiration high-pitched and forcible, and expiration prolonged, blowing, and cogwheel in character. The accessory muscles of inspiration acted strongly. The cardiac action was rapid and forcible; the arterial tension was high. The cardiac sounds were obscure. There was no bruit detected. On the day of admission patient had three attacks of dyspnoea, each of which lasted from five to twelve minutes, and during which the respiration was very greatly embarrassed and the face was very cyanotic. These attacks were at first relieved by bromide of ammonia and chloroform vapor, but later they were not influenced favorably by these drugs. Examination of the urine showed a trace of albumen, granular casts, and blood. His temperature was normal. First night in the hospital he had several slight attacks of dyspnoea (none of them severe), and on the morning of March 5th, his temperature was 98.1° F., his respiration 18 per minute, and his pulse 76. The left radial pulse was markedly less forcible than the right. The pupils were equal, and there were no symptoms of paralysis. In the afternoon he had a severe and prolonged attack of dyspnoea, during which respiration was suspended for a time.

"Laryngotomy was performed and a tube was inserted through an opening made in the crico-thyroid membrane, but this gave no relief. A stiff catheter, No. 12, English, was then inserted through this opening, into the trachea to the distance of five and a half inches, and by this means respiration was established. A note on the 5th describes a tumor above the clavicle on the right side. On

deep palpation there is pulsation, and over its site a distinct systolic murmur is heard, which is audible in the cervical vessels. During the night, temperature rose to 104.6° ; respiration, 25; and pulse, 128 per minute. During the 6th he suffered for lack of oxygen and an unsuccessful effort was made to introduce a larger catheter. The smaller one then was reinserted. He became more and more cyanotic, gradually sank, pulmonary oedema developed, he became moribund, and died on March 7, 1883, at 2.40 A.M.

"The highest temperature was 105.2° , his respiration 34, and pulse 160 per minute.

"He was treated with whiskey and digitalis.

"Autopsy on March 7th, at 2 P.M.—The body was well nourished. There was an incised wound in the median line of the neck, one and a half inch in length, dividing the crico-thyroid membrane. There was a small amount of serum in both pleural cavities. The lower lobe of the right lung and a part of the lower lobe of the left lung were in the condition of red hepatization, and the pleura covering the hepatized parts was covered by recent lymph; lungs elsewhere were intensely congested. The spleen, kidneys, stomach, and intestines were normal. The liver was pigmented, but otherwise normal. Heart and aorta: The heart is normal in size; its cavities contain recent clots. The cusps of the aortic valve are thickened and retracted, other valves are normal. The aorta throughout is atheromatous. There is a circular opening in the arch of the aorta, three-fourths of an inch in diameter, between the innominate artery and the left common carotid. This opening communicates with an aneurismal sac rising above the upper wall of the aortic arch two inches, the transverse diameter is two and one-half inches. It contains laminated fibrin and recent clots. The innominate artery communicates with the sac, partially arising from the lower right side of it. The left subclavian artery admits a cylinder one-fourth of an inch in diameter, while the corresponding artery on the right side admits a cylinder nearly one-half inch in diameter. There is a growth in the wall of the left subclavian artery, just above its origin, one-eighth of an inch in thickness, which is situated between the intima and media. This growth is lenticular in shape, its long diameter, parallel with the long axis of the artery, is one-half an inch, and its short diameter is one-fourth of an inch. It is made up of white fibrous tissue, small, round, and spindle cells.

The Society then went into executive session.

LIGATURE OF THE BILE-DUCT.—Beloussow has studied this subject under the direction of Cohnheim and Weigert. He experimented upon rabbits, guinea-pigs, and dogs. The longest time that any animal survived was eighteen days. The liver was jaundiced and slightly enlarged. In its substance were seen yellowish gray spots, varying from the size of a pin's head to a pea. These were most numerous from the first to the sixth day. The microscopic examination showed them to represent a partial necrosis of the liver substance caused by the pressure of the bile. Around these nodules appeared a zone of reactive inflammation with the formation of young connective tissue in which were newly formed bile-ducts. This new tissue gradually replaced the necrotic portions entirely. In this way is to be explained the cirrhosis of the liver observed by earlier experimenters (Wickham, Legg, Charcot, Gombault, and others) after the ligature of the ductus choledochus. This occurred in entirely aseptic cases, and was in no way to be connected with any inflammation starting from the point of ligature and following up the course of the bile-ducts. Kelsch (*Rev. de Méd.*, 1881) records two cases where the retention of bile was followed by cirrhosis—one following closure of the duct by cholelithiasis and cancer of the gall-bladder, the other in which a dilatation of the bile-ducts was found without any formation of concretions.—*The Practitioner*, March, 1883.

New Instruments.

A NEW HYPODERMATIC SYRINGE.

BY FRANK SARGENT GRANT, M.D.,
NEW YORK.

Description.—The illustration shows the size, in and out of the case. The syringe is of glass, with hard rubber fittings, and holds ten minims of fluid when fully charged. The piston is of the dumb-bell kind, and works smoothly in a *uniform* bore. The piston-rod is made larger than usual, in order to insure *an easy and steady action*. The steel needle drops into the top of the piston-rod when not in use. A little vaseline placed in the rod will effectually prevent rusting of the needle. The syringe screws on to a glass vial with a capacity of a little over ten minims, and should be always filled when not in use, as by this means the leather packing on the rod is *constantly kept moist and in working order*. Both syringe and vial screw into a hard rubber case, and thus can be carried in the vest pocket. At the bottom of the case is a receptacle for holding the various hypodermatic preparations now in the market.

Directions.—Unscrew vial from syringe at A; fill *almost full* with solution or water, leaving only an air-bubble to act as an air-chamber, and rescrew on to syringe firmly. Now invert instrument and draw solution into syringe; unscrew vial at B, attach needle, and the instrument is ready for use.

If desirable, the physician can have the instrument ready for an injection at a moment's notice, by previously dropping into the vial a powder or globule of given strength. For such a purpose I have found the hypodermic "globules," as manufactured by Wm. R. Warner & Co., most reliable and quickly soluble.

The hypodermatic syringe is made by John Reynders & Co.

11 WEST FORTY-FIFTH STREET.

A KEY RING ARTERY CLAMP.

BY BREWER MATTOCKS, M.D.,
FARIBAUT, MINN.

In the routine practice of surgery—especially in the country, where one rarely has experienced assistance—delay, annoyance, and chagrin invariably attends the ligature of arteries; and even in town, where one may avail himself of experienced surgical friends, sooner or later the exclamation is breathed, "good surgeon but poor assistant." If this be true of operations involving a surgical staff, how much more trying is the ligature of arteries where one has no assistance whatever, as frequently happens in the office, or in cases of emergency.

Ten years ago, after working alone with my patient over a small artery for a long time, it occurred to me, "If I could but put a split ring on an artery?" I could not, however, until recently.

This cut explains the instrument I have devised, and

suggests its application perfectly. With a set of these clamps—they should be had in sets of six or more—one may apply them to the arteries in a capital operation himself, and ligate at leisure; or one may be applied to a single artery till bleeding has been controlled, or until one may turn to his table for a ligature, without fear of its weight pulling it loose; or one may *fish* for a wounded artery with the clamp, and the artery having been secured it may be left in position for several days if thought best. It is nickel plated. To sum up its advantages:

First.—It is self-holding, and its lightness will not cause it to tear loose, and its shape is perfectly adapted to slipping the ligature to its place.

Second.—With the clamp one is enabled to operate with no assistance when necessary.

Third.—In cases of emergency one may be attached *blindly*, and left in position.

Fourth.—If a pair be placed upon a physician's key-ring he will always have a convenient and ready means of controlling hemorrhage from a wounded artery.

Fifth.—While it would be idle to claim that this clamp will supersede the use of the forceps, I may claim that a set of them will multiply the uses of his forceps tenfold.

Sixth.—May I make the claim that a surgical instrument may be constructed so simply that any one may understand its application, and so cheaply that its cost will not be a bar to its use?

A NEW NASAL SPECULUM.

By WM. C. JARVIS, M.D.,

NEW YORK.

A CAREFUL and satisfactory trial has induced me to present to the medical profession a new nasal speculum.

Its simplicity in principle and construction as shown in the figure, drawn full size, makes an extended explanation unnecessary. It is represented as half-opened.

The arms of the speculum, pivoted in the centre, are encircled by a small ring.

The instrument is readily introduced into the nostril when the blades are closed. Gentle pressure upon the handles separates the blades and at the same time permits the ring to drop and keep them open. The tension of the speculum can be very nicely regulated by this arrangement, and a very light pressure is sufficient to retain them in the nostril.

It does not irritate the nose even when used at short intervals on the same person. Indeed, patients sometimes forget the presence of the instrument in the nostril.

This is an important advantage in view of the severe excoriation and fissure which has followed the frequent use of most self-retaining nasal specula.

Mr. W. F. Ford has constructed the instrument in several shapes with skill and at little expense. He informs me that he can furnish eye, vaginal, and anal specula working on the same *ring-drop* principle.

I take this opportunity to communicate with the many correspondents who have encouraged me by their success in the practice of my operations, and believe they will find that this little instrument facilitates the use of the *écraseur* in the anterior nares.

123 EAST TWENTY FIFTH STREET.

CANNABIN TANNICUM AS A HYPNOTIC.—Hiller confirms the statements of Froumüller that the tannate of cannabin is a good hypnotic in the milder forms of insomnia. The dose is 0.3 to 0.5 gramme.

Obituary.

PHILIP HARVEY, M.D.,

PORTLAND, ME.

DR. PHILIP HARVEY, Professor of Diseases of Women and Children, Willamette University, died in Portland, Oregon, March 23d, in the seventy-ninth year of his age. He was born in England, pursued the study of medicine, and graduated in that country. He traced his descent to the family of William Harvey, the discoverer of the circulation of the blood.

During early manhood he came to the United States and commenced practice in Brooklyn, N. Y., where he became one of the physicians to the Brooklyn Dispensary. Believing that a larger field was open to him in the West, he moved thither and practised for some years in Cincinnati. During that period he published a treatise on "Food and Climate," a work of much learning, originality, and research. Afterward he was induced to remove to Iowa, where he edited, with marked ability, the *Burlington Gazette*, making it a model newspaper, and greatly increasing its circulation. He was appointed and reappointed Surveyor of the Port, and notwithstanding the absorption of much of his time by the duties of those positions, he wrote considerably, made investigations on scientific subjects, and carried on a large practice. Soon afterward he accepted the chair of Theory and Practice in the University of Iowa, which he held at the outbreak of the rebellion. Politically he subscribed to the doctrines of the Jeffersonian Democracy, but throughout the entire war was a staunch Unionist. He received early in the struggle the commission of surgeon of an Iowa regiment, and was continuously on duty at the front or in hospital from that time till the cessation of hostilities, when he retired as Lieutenant-Colonel and Surgeon of Volunteers.

About eight years ago he went to Oregon in search of relief from asthma. There he at once became identified with the medical school, as teacher and consultant, lecturing and writing much upon medical and scientific subjects.

He was a profound scientist and Shakesperean scholar. His memory was remarkable; he could repeat word for word, whole pages after one perusal. He was a man of extremely abstemious and simple habits, of high moral rectitude and general impulses. Sympathetic and conscientious in his professional life, he was at all times ready to sacrifice his personal ease, health, or prospect of gain at the call of duty. He knew several languages well, and had some acquaintance with many, was an excellent musician, and possessed considerable artistic ability.

His widow survives him at the age of sixty-nine. Also two sons, George Harvey, an artist, and Dr. Philip F. Harvey, U. S. A., and one daughter, Mrs. E. P. Rogers, of Portland, Maine.

ANOTHER DEVICE FOR PREVENTING THE BREAKING OF THERMOMETERS.—Dr. James Bordley, of Centerville, Ohio, writes regarding this much-agitated matter: "The device is nothing more nor less than an *old* style pencil-holder, with pin for attaching. Secure it by its pin just within the upper pocket of the vest, and I am sure there will be no further complaint, for it is satisfactory in every respect, answering the purpose much better and at less cost and trouble than anything I have tried or seen offered.

"I would suggest that some instrument-maker (or some one else) manufacture them especially for the purpose, making them a little stronger than they are usually made for pencils, with such other slight modifications as might more perfectly adapt them for this vicarious function."

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 24, 1883, to March 31, 1883.

BARNETT, RICHARDS, Captain and Assistant Surgeon. To proceed to Fort Adams, R. I., and report to the commanding officer for duty at that post. S. O. 51, par. 1, Department of the East, March 28, 1883.

CRONKHITE, HENRY M., Captain and Assistant Surgeon. Relieved from duty at Fort McKinney, Wyo. Ter., and assigned to duty as Post Surgeon at Fort Fred Steele, Wyo. Ter. S. O. 31, Department of the Platte, March 22, 1883.

DE LOFFRE, AUGUSTUS A., Captain and Assistant Surgeon. Granted leave of absence for three months. S. O. 71, par. 3, A. G. O., March 27, 1883.

LORING, L. Y., Captain and Assistant Surgeon. To proceed without delay to Fort Schuyler, N. Y. H., and report to the commanding officer for duty as Post Surgeon. S. O. 51, par. 2, Department of the East, March 28, 1883.

MOSELEY, EDWARD B., Captain and Assistant Surgeon. To report in person to the President of the Army Medical Examining Board in New York City for examination for promotion, and upon completion to return to proper station. S. O. 70, par. 3, A. G. O., March 26, 1883.

PAULDING, H. O., Captain and Assistant Surgeon. Relieved from duty at Fort Laramie, Wyo. Ter., and assigned to duty at Fort Sidney, Neb. S. O. 31, Department of the Platte, March 22, 1883.

SKINNER, JOHN O., Captain and Assistant Surgeon. To report in person to the President of the Army Medical Examining Board in New York City for examination for promotion, and upon completion to return to proper station. S. O. 70, par. 3, A. G. O., March 26, 1883.

TAYLOR, MARCUS E., Captain and Assistant Surgeon. To report in person to the President of the Army Medical Examining Board in New York City for examination for promotion, and upon completion to return to proper station. S. O. 70, par. 3, A. G. O., March 26, 1883.

TURRILL, HENRY S., Captain and Assistant Surgeon. Relieved from duty at Fort Fred Steele, Wyo. Ter., and assigned to duty as Post Surgeon at Fort McKinney, Wyo. Ter. S. O. 31, Department of the Platte, March 22, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 3, 1883 :

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
March 24, 1883	0	10	113	6	102	52	4	0
March 31, 1883	0	9	125	7	96	52	2	0
March 31st to April 3d..	0	4	53	6	29	16	0	0

Deaths from contagious diseases from March 31st to April 3d, inclusive, are scarlatina, 8; diphtheria, 8; typhoid fever (emigrants), 2; cerebro-spinal meningitis, 5; measles, 7.

THE VOTE OF THE NEW YORK STATE MEDICAL SOCIETY.—That the vote of the Society fairly represents the sentiment of the entire State at the present time seems, further, to be pretty certain. During the summer the secretary of the society addressed a card to members of the county societies asking for the vote of individuals upon the question. To this he received about seven hundred replies, of which three hundred and sixty were in favor of the new code, a small number were non-committal, and the rest were opposed to it. This vote, which in its way fairly represents the prevailing feeling, tallies quite closely with that of the assembled representatives of the county societies and permanent members. More than half the counties, moreover, were directly represented by instructed delegates, many of whom were compelled to vote against their individual convictions. It is altogether probable that a free vote to-morrow would result in a larger majority, and that each passing day would add to it.—*Medical Annals.*

BEEF-TEA.—Dr. Ridges gives the following directions for preparing an article which really is what it purports to be, and far superior to any of the so-called extracts of meat: 1. Take one pound of lean gravy beef and cut it into pieces as small as possible. A sausage-machine will accomplish this most thoroughly, and thus save half the time of step No. 5, while it will enable you to extract all the goodness of the meat more thoroughly. 2. Place the meat in a preserve jar with one salt-spoonful of salt, and put the jar in a saucepan sufficiently large to allow the lid to be placed on when the jar is in it. 3. Mix in a large jug equal quantities (carefully measured) of boiling water and cold water. 4. Put half a pint of this mixed water into the jar which contains the meat, and pour sufficient of the remainder into the saucepan outside the jar to reach as high as the water inside the jar, then put the lid on the saucepan and place it on the hearth, not on the fire or on the hob. It will do no harm to cover the saucepan with a cloth or anything which will keep in the heat. 5. The meat must remain in the jar from three-fourths of an hour to two hours, according to the fineness to which it has been chopped, being stirred every quarter of an hour. If cut into pieces a little smaller than dice, one hour and a half will be sufficient. At the end of this time take out of the jar and strain through a hair sieve, or through muslin, with gentle pressure. 6. Place the red meat-juice thus obtained in a small saucepan, and heat it to boiling while you stir. It will turn brown and curdle. Strain off the solid flakes and rub these thoroughly with a small teaspoonful of arrowroot or corn flour, then boil these again five minutes with the liquor which was strained off, and set it on one side for the present. 7. Now take the meat which was left in the sieve at the end of step No. 5, and put it into a saucepan with a quart of boiling water, cover, and let it simmer over a slow fire for three hours; then allow it to boil and strain immediately. 8. Now boil this strained liquor down to half a pint. 9. Then mix this half pint with the half pint left at the end of step No. 6, and you will have one pint of strong beef-tea containing all the soluble portion of the meat.

"HOW MANY DOCTORS ARE THERE," says Montaigne, "who disdain medicine in their own persons, following a free sort of life very different from what they recommend to others? What is all this but abusing shamefully our simplicity? For their life and health are as dear to them as they are to us, and they would accommodate their proceedings to their doctrines if they did not know their falseness."

GAMBETTA'S BRAIN AGAIN.—It is claimed by Prof. W. Krause of Göttingen, that the true weight of Gambetta's brain was not 1,160 grammes as reported. Soon after death the arteries were injected with a zinc chloride solution. This solution extracted the water from the brain and lessened its weight according to Prof. K. He estimates its true weight, at 1,320 grammes. There may be some truth in this view, but not much.

THE LATE PROFESSOR POND was once demolishing Darwin and his theories—a task which he frequently engaged in—when he triumphantly wound up with the question: “If we are monkeys, where are our tails?” The professor, who had been speaking for two hours at a stretch before asking this poser, was startled to hear a tired auditor answer audibly: “We have sat on them so long that they are worn off.”

A NEW REMEDY IN THE TREATMENT OF SYPHILIS is described by Dr. J. Marion Sims in *The British Medical Journal*. It consists of fluid extracts of *smilax sarsaparilla*, *stillingia sylvatica*, *lappa minor*, *phytolacca decandra*, and a tincture of *Xanthoxylum carolinianum*. The *s. sylvatica* (queen's delight) is thought to be the active drug. It has long been used in the South against syphilis by the Indians and negroes. It has also been introduced and used by Drs. McDade and Rush Jones. Some remarkable instances of its efficacy are given by Dr. Sims.

THE INDICATIONS FOR THE USE OF DIGITALIS in heart troubles are empty arteries, full veins (Fothergill). The bulk of urine is the index of arterial fulness, and tells whether digitalis is acting (Traube). Digitalis fills the arteries and empties the veins (Rosenstein).

A PROSPECT OF CHOLERA IN THE SOUTHWEST THIS SUMMER.—Dr. Ludeking, clerk of the Board of Health of St. Louis, has found that cholera ravaged that city in 1849 and in 1866, and was each time preceded by very high water in the Mississippi. As another seventeen years has passed, and the premonitory high water is at hand, he will not be astonished if the disease becomes epidemic again next summer. It must be added, he says, that before the cholera made its appearance in the West, it each time visited Asia, and thus far Asia is uncommonly free from it. The latter statement, sad to say, is not true, judging from recent accounts.

A CLASS QUIZ ON ANATOMY—NEW POSITIONS FOR THE AORTA AND NEW RELATIONS FOR THE PANCREAS.—A correspondent from Chicago writes: “Frequently short articles have appeared in THE RECORD and other medical journals alluding to and praising the excellent laws which regulate medical practice in Illinois. Perhaps the operation of these laws does not exclude ignorant quacks from the State as well as distant observers may suppose. Allow me to speak of a visit I made one of the *recognized* medical colleges of Chicago a short time before the end of its term. The subject of the hour happened to be a quiz on anatomy by the regular lecturer. As soon as the throwing of orange-peels had ceased and the embryo male and female doctors had become somewhat quiet, the lecturer began to ask about the abdominal aorta. Although there was a diagram of the vessel in front of the class, and many of the students had Gray's open before them, yet much difficulty was experienced in determining the location of the artery. Of the half of the company who answered at all, some held that the vessel was behind the sternum, one said it supplied the heart, and one man carefully affirmed that it was located one inch to the left of the left nipple. Like results were obtained when the quiz on the branches was reached. Perhaps a climax of ignorance occurred when one man said that the gland on the tip of the coccyx was the pancreas. These answers fairly represent four-fifths of those given during the hour. This is one of the recognized colleges whose diploma is gladly given to any one who has taken two five months' courses of lectures. Between four and five hundred diplomas are granted each year in this city, and very few of the graduates have taken more than two short courses of study. Entrance examinations are unknown. These conditions do not tend to make an Illinois student especially proud of his chosen profession. Likewise there seems little possibility of improving the condition as long as diplomas are recognized as licenses.”

PROFESSOR RILEY ON MIND IN PLANTS.—At a recent weekly lecture at the National Museum, under the joint auspices of the Biological and Anthropological Societies, delivered by Professor C. V. Riley, the subject was, “Do Plants have Mind.” He first spoke of insectivorous plants which derive nourishment from the animal mould, and his ideas as to the allurements of insects by plants in order to secure cross-fertilization were elucidated by numerous illustrations of both plants and insects. He described the movements of many plants as voluntary and the actions of many insects as rational. In concluding, the Professor said: “One thing is certain and profoundly significant, viz., that the lowest organisms and the first existant on our planet possessed at some state of development the power of independent motion—activity. It matters little whether we call them animals or plants; they were, and their present representatives yet are, perhaps, combinations of both. They represented the potentiality which has developed on the one side the most complex animal intelligence, and on the other the highest vegetative organization.”

THE INCOMES OF LONDON PHYSICIANS.—Our London correspondent writes: “Few London physicians can earn more than £1,200 a year, even by the most unremitting labor. The number of London practitioners who make more than £10,000 a year in practice is probably less than a dozen. In the pre-railway days, however, when large fees were paid for long distances, physicians did occasionally receive very large fees. It is stated that the late Dr. Jeaffreson, of Leamington, earned considerably over £10,000 a year for many years, and that one year he actually realized in practice the large sum of £20,000.”

THE ASSOCIATION OF AMERICAN MEDICAL EDITORS.—The next annual meeting of the Association of American Medical Editors will be held in the city of Cleveland, Ohio, simultaneously with that of the American Medical Association, on June 5 and 6, 1883. An address will be delivered by the President, Dr. N. S. Davis, Chicago, on “The Present Status and Tendencies of the Medical Profession and Medical Journalism.” A free discussion upon this important subject is invited, which will be open, not only to members, but to all physicians present. Dr. Marcy will also present the subject of “Journalism Devoted to the Protection and Concentration of Medical and Surgical Science in Special Departments.” Special papers by Dr. John A. Octerlony, of Louisville, Ky., and Dr. Alexander J. Stone, of St. Paul, Minn., are also promised.

THE RESULTS OF RESECTIONS OF THE PYLORUS FOR CANCER, as given by Rydygier, are as follows: Sixteen surgeons have operated upon twenty-three cases, all but two of which have been examples of cancer. Of these last two operations one was performed by Rydygier in a case of stenosis, caused by round ulcer, which terminated successfully; and the other by Lauenstein in a case of supposed cancerous tumor, which at the autopsy proved to be one of gangrene of the transverse colon. Of the twenty-three cases nineteen proved fatal, viz., fifteen some hours after operation, three on the seventh or eighth day, and one (Billroth's) four months after from relapse. Of the four recoveries, one belongs to Billroth (no relapse having occurred in six months), one to Wolf-ler (the patient seeming well at the end of a year), one to Czerny (seven months without a relapse), and one to Rydygier.—*Medical Times and Gazette*.

MOUNTAIN FEVER, so called, is thought by Dr. B. P. Anderson (*Denver Medical Times*) to be due not to malarial infection or influence, but probably to accumulated secretions from the liver, kidneys, and skin. He believes that a dose of calomel or blue pill taken every two or three months, with the practice of frequent bathing, would so thoroughly prevent this disease that physicians would seldom be called upon to treat it.

The Medical Record

A Weekly Journal of Medicine and Surgery

NEW YORK, APRIL 14, 1883

Whole No. 649

Original Articles.

ON VARIOLA.

ITS DEFINITION, HISTORY, CAUSE, VARIETIES, PROGNOSIS, AND TREATMENT.

By J. N. MCCHESENEY, M.D.,

LATE ONE OF THE ATTENDING PHYSICIANS TO THE HOSPITAL FOR CONTAGIOUS DISEASES OF THE CITY OF NEW YORK.

(Continued from page 369.)

Treatment.—The treatment in small-pox is of two kinds: prophylactic or preventive, and measures, local and general, addressed to the symptoms as they occur, in other words, the expectant method. Small-pox once contracted can neither be cut short nor the course of the eruption modified by any plan of treatment that we know of. In mild, discrete cases little or no treatment except ordinary hygienic measures will be needed. Patients are often not ill enough to keep their bed, and, if they can be kept away from others, are benefited by exercise in the open air. This, of course, is only permissible when they are so situated that out-door exercise will not bring them in contact with other persons.

For the first few days, during the initial stage, we cannot be certain what febrile disease is approaching, since the symptoms of this stage are similar in many respects to those of other acute eruptive troubles, and the same general measures are to be adopted. For the fever, cooling acidulated drinks; if the bowels be constipated, they should be opened. Active cathartics are to be avoided, and enemas, or the milder laxatives preferred. The effervescing salines, such as the citrate of magnesia, seidlitz powders, Rochelle salts, or some one of the aperient waters, will act sufficiently and prove agreeable, as well as have a tendency to allay the nausea and vomiting attendant upon this stage. Sponging of the body with cool or tepid water reduces the temperature, and renders the patient comfortable. Quinine to allay fever is of but little use in this stage; it is rarely retained and generally increases the irritability of the stomach.

Headache may be relieved by cold cloths—occasionally cloths wrung out of water as hot as can be borne prove more acceptable. The bromides, combined with chloral in an aromatic vehicle, are useful if there is restlessness and delirium; if they prove inefficient a small amount of morphia may be added. If diarrhoea be present—as it occasionally is, more especially in children—the ordinary *mistura creta*, alone or with some one of the vegetable astringent tinctures in combination, is frequently sufficient to check it. We have had much satisfaction from the use of the fluid extract of *coto bark*, alone or with an aromatic syrup, giving twenty minims every half hour till three doses have been taken; this quantity is usually sufficient. If these remedies do not suffice some of the more powerful astringents may be resorted to; the mineral astringents combined with opium in pill, or given per enema, should be tried.

The nausea and vomiting, which is one of the most persistent and disagreeable symptoms of this stage, is very difficult to relieve. Small lumps of ice, swallowed whole, relieve the thirst and allay nausea; lime water, carbonic water, taken in small doses, is frequently retained. One-eighth to one-sixth grain morphia, hypodermically, in the epigastric region, is frequently success-

ful. Mustard applied to the stomach is useful, but it is to be remembered that counter-irritation brings out the eruption, and vesication takes place very easily. The numerous remedies for this condition may all be tried—the simplest will often prove the most efficacious.

Another obstinate and distressing symptom is the intense pain in the lumbar and sacral regions. The patient will often complain of this and beg to be relieved. The sponging and bathing which reduces the temperature often affords some temporary relief. A sponge wrung out of water as hot as can be borne and placed on the back gives ease. It should be changed as often as it becomes cool. Mustard poultices may be used, but are open to the objection above mentioned. Dry cupping is worthy of trial. Morphia hypodermically may be necessary.

The diet during this stage should be light and easily assimilable, consisting of milk, rice, corn-starch, and like articles.

After the appearance of the eruption all of these symptoms, as a general rule, are either greatly ameliorated or disappear entirely; the patient feels so well that for a few days little or no treatment is required.

As soon as the nature of the disease is determined—if the case occur in a town or city—the health authorities should be notified, and if the most perfect isolation and quarantine is not possible at the patient's home, he should be removed at once to the small-pox hospital, or to some isolated building set apart for the purpose.

The isolation of patients at their homes is always a questionable measure, and keeping a case in houses where there are more than two small families should never be permitted. If small-pox be prevalent or a history of exposure can be obtained, or there are any other grounds to justify suspicion of variola, even in the stage of invasion, strict isolation should be enforced from the beginning.

When the diagnosis has been established, the first steps to be taken, after the isolation or removal of the patient, are to protect all those who may have been exposed in the slightest degree. This is to be accomplished by thorough vaccination and revaccination of every person in the house where the case occurs, and all of those living in the vicinity. The persons living in the house and neighborhood should be visited every second day, and kept under the closest surveillance for two or three weeks after the removal or recovery of the case.

If the patient is to be treated at his home, a large, well-ventilated room, at the top of the house, with an open fire-place, should be selected. The carpets, and all unnecessary furniture, should be removed; the bed should be firm, a hair mattress is preferable; a sufficient supply of linen for frequent changes, both for the patient and his bed, and all other articles for his use should be set aside and kept apart. Old pieces of muslin for handkerchiefs will be useful for cleansing the mouth and nostrils of the patient; they can be burned after using. An adjoining room, opening into that occupied by the patient, should be prepared for the use of the attendants, whose isolation must be almost as strict as that of the patient. We do not mean that they should not be allowed exercise and fresh air, but the promiscuous mingling with the family or others, even for the shortest time, without proper disinfection and change of their infected clothing, should be enjoined. The attending physician should be equally careful as to his person; he should provide an old suit of clothing and a calico wrapper, or linen duster, to go over

all; these should be kept in the adjoining room, to replace his own clothing when he makes his visits. A rubber coat and shoes are frequently used, but these are cumbersome and impede the movements more than lighter garments. Disinfectant materials and solutions should be kept in saucers around the rooms, and in the vessel into which the discharges from the patient are passed. The best for this purpose are Labarraque's solution, crude carbolic (crystalline) acid, and a solution of sulphate of iron (copperas), one pound and a half to the gallon of water. For washing the hands and bathing purposes, we prefer tar to carbolic soap.

If the attack proves to be of a mild form, with a discrete eruption, little or no treatment will be necessary except that of a hygienic kind; but if it prove to be one of the more severe forms of the disease with an abundant eruption, there will be many distressing symptoms throughout its course which may be alleviated.

The symptoms which occasion the most discomfort in the stage of eruption, are those caused by the presence of the eruption on the mucous membranes of the throat and larynx, the œdema of the face, especially of the eyelids; and the smarting pain of the whole surface.

The œdema of the eyelids and face is soonest relieved by the constant applications of compresses, wrung out of hot water. They should be frequently changed, and never allowed to become cool. For the smarting of the surface, vaseline or cosmoline applied cold is preferable to any of the various cold creams, ointments or salves. The former are perfectly bland and do not become rancid. The throat symptoms give most trouble and are most complained of. It is necessary to explain to the patient that the presence of the eruption on these parts is the cause of the distress, and that we are unable to check its development. For this, the various gargles of flax-seed tea, solutions of the chlorate of potassa, alum, or borax, may be tried. We have used almost every form of gargle, and have had more satisfaction from bromo-chloralum than anything else; it gives relief quickly and for a longer time. Small lumps of ice, allowed to dissolve in the mouth, are usually very grateful to the throat. Hot moist applications externally around the throat sometimes give comfort. The inhalation of steam, and the use of astringent solutions, applied by means of a spray, will often prove useful.

For the conjunctivitis, cold compresses and astringent collyria have been recommended to allay the inflammation and lessen the liability to development of the eruption on the conjunctiva. We have found weak solutions of alum useful for the conjunctivitis, and have also used solutions of atropia (ij.-iv. grs. to $\frac{z}{j}$.) with good effect when there is pain and photophobia. As to preventing the development of the eruption on the conjunctiva, we have not been able to accomplish so much, but think that prompt treatment will prevent ulceration and perforation of the cornea.

The intense pain caused by the distention of the vesicles in the palms, on the finger-tips, and in the soles of the feet is relieved by soaking the hands and feet in hot water for fifteen or twenty minutes at a time, and then puncturing the vesicles and allowing their contents to escape. The large blebs or bullæ so often seen in the confluent eruption frequently burst, or become broken, leaving large raw exuding surfaces; these should be dusted with some fine dry powder—bismuth and oxide of zinc is best for this purpose; lycopodium may also be used.

The great restlessness and prostration, which often comes on early in the severe forms of the disease, must be met with stimulants and anodynes, in conjunction with nutritious and easily assimilable food. When the eruption is abundant, and the suppuration likely to be extensive and protracted, supportive measures should be resorted to early in the treatment of the case. The use of stimulants should be commenced early and administered regularly throughout the suppurative stage, and continued until

convalescence is established; the form and amount should be governed by the indications furnished by the pulse.

In the stage of secondary fever, should the temperature rise very high, say 103° F., the patient will become very uncomfortable, restless, and delirious, and be continually trying to get out of his bed. If the temperature be reduced he becomes more comfortable, and frequently falls asleep. We have tried large and frequent doses of quinine under these circumstances, and had such poor satisfaction from its use that we ceased to give it, preferring to rely upon the use of cold sponging, the wet sheet, or the use of the Kibbee cot.

The latter measure we have found both agreeable and effective in reducing the temperature and allaying restlessness and delirium. If the patient be a child, or a person of delicate constitution, sponging, or the pack, is to be preferred to the cot. We should always begin with the water barely tepid, and continue its use till the temperature falls to about normal. The addition of alcohol to the water for feeble subjects is of advantage. In persistent high temperature, after sponging and the wet sheet have been tried, the use of the Kibbee cot will often prove effectual. It may be necessary to resort to the use of anodynes and sedatives to insure quiet and sleep. The bromides, chloral and morphia, will prove useful. Care should be exercised in the administration of anodynes to those cases where there is copious formation and expectoration of viscid mucus; if the patient should fall asleep, the accumulation may go on in the air-passages to such an extent as to interfere with respiration, and may produce asphyxia.

The diet throughout this stage should be as nutritious and easily digested as possible, it may consist of milk, beef-tea and other meat-broths, eggs, gruel, etc. Stimulants may be given alone, or in the form of egg-nog or milk-punch.

When the pustules break and their contents escape over the surface, there is burning and itching of the skin, which is very annoying to the patient. This is generally allayed by frequent use of carbolyzed baths, after which the skin may be freely anointed with vaseline. The odor at this stage of the disease is peculiar and very offensive; for this we have found Labarraque's solution, solutions of the permanganate of potassa, and bromo-chloralum much preferable to carbolic acid.

In the hot months care must be exercised to prevent the large green flies from depositing their eggs in the pustules; these, once deposited, are in the most favorable condition for development into larvæ, which, when developed, burrow into the pustules and ulcers, make their way into the nose and ears, and thus occasion much annoyance. A strong solution of permanganate of potassa, liberally applied, is the best method of exterminating them and of preventing their return.

When desquamation is established and the temperature subsides, if suppuration has been extensive, and the patient in an asthenic condition, tonics, such as iron and quinia, with the bitters, should be given, with a nutritious diet, and the use of stimulants. During convalescence wine, ale, beer, and porter are useful. All of the hygienic surroundings of a patient suffering from small-pox should be the very best possible; free ventilation is especially important, but care should be taken not to expose the patient to currents of air and thus incur the risk of getting up a pleurisy or pneumonia.

During the stage of desquamation frequent warm baths give comfort to the patient and promote the falling off of the crusts. The ulceration on the face, about the cheeks and wings of the nose, is frequently prolonged; the scabs are unusually adherent, confining the pus beneath them, which has a tendency to increase the ulceration. The crusts should be soaked with hot water, or softened by vaseline, and removed, and applications made directly to the bottom of the ulcers. The best application that we have used in this condition is iodoform and balsam of Peru, thirty grains to one ounce. Patients, especially

females, and their friends are always anxious about the pitting and danger of disfiguring of the face, and they will beg of you to do every thing to prevent it. Numerous remedies have been used to prevent pitting, with varied success claimed for each by its advocate. The following list is given by Professor Flint :

1. "The careful evacuation of the vesicles by means of a fine needle." This calls for much patience, both on the part of the patient and the physician, and may be useful when the eruption is scant—under which circumstance there would be little or no pitting anyway. Where the eruption is confluent the undertaking would be an endless one, far exceeding the patience of the operator or the endurance of the patient, and the amount of benefit not at all commensurate with the time expended.

2. "Evacuation of the vesicles, and cauterization by means of a fine-pointed stick of nitrate of silver." This too is a tedious process and open to the above objections. In mild cases this method may possibly shorten the time of quarantine, and may be resorted to for that purpose.

3. "The application of the tincture of iodine, once or twice daily, by means of a brush, while the eruption is papular." This has been claimed to diminish the size of the vesicle and lessen pitting. We have given this plan a trial in a number of cases, and the results were not at all satisfactory. It causes severe smarting, and occasionally produces considerable swelling.

4. "The exclusion of light and air. This is done by covering the face with a plaster of some kind." We have not found that this lessens the amount of eruption, or sufficiently diminishes suppuration to alter the result.

5. "The application of a mild, mercurial ointment, spread on cloth, or of compresses dipped in a solution of corrosive sublimate (gr. ij. to iv., to water $\frac{5}{8}$ vj.)." The risk of producing the constitutional effects of mercury is an objection sufficient to condemn this plan.

6. "The application of subnitrate of bismuth and prepared chalk in equal parts, twice daily, after smearing the surface with sweet-oil."

7. "The application of poultices over the face, beginning at the earliest period and continuing to the advanced stage of the disease."

8. "Solutions of collodion or of gutta-percha, painted on the surface twice daily by means of a brush. This should be done in the papular or early vesicular stage." Our experience with these remedies has been the reverse of satisfactory. The contraction produced by the drying of the solutions is much complained of by the patient. If they be kept up in the later stages of the disease they confine the discharge, produce a very offensive condition of the patient, and increase ulceration.

9. "Carbolic acid, liquefied by alcohol, and applied by means of a camel's-hair brush as soon as the contents of the vesicles appear puriform." This is recommended by Lister to lessen the amount of suppuration. He also advises the following paste: Carbolic acid, four to ten parts; olive-oil, forty parts; prepared chalk, sixty parts.

10. "Compresses, wet with cold water, are applied by many and regarded as useful."

In deference to the wishes of patients and their friends, it is always well to make a trial of some of these methods, but it will be prudent not to encourage them to expect too much in the way of results. After a faithful trial of nearly all of the methods enumerated above, we have come to the conclusion that the amount of pitting in each case will be in proportion to the amount of eruption and destruction of true skin. If the pustules are superficial the scars will be slight; if the true skin is involved, pitting will occur in spite of all the preventive measures that may be used.

The brown staining of the skin from the eruption, which at first is so plain, soon fades, but the pitting becomes more perceptible some time after the patient has recovered.

Pneumonia, pleurisy, and bronchitis, are to be treated

according to the indications for the management of these affections occurring primarily, bearing in mind always that the tendency to asthenia is greatly enhanced by the presence of small-pox. Erysipelas we have best met by the internal exhibition of large doses of the tincture of the chloride of iron with quinine, and a generous nutritious diet; locally, by the application of the tincture of iron over the whole of the surface involved, and painting with the tincture of iodine a broad margin around the inflamed skin to prevent its extending. If there is a tendency to suppuration, hot poultices should be continuously applied, and as soon as evidence of fluctuation is detected free incision should be made.

For the corneal ulceration we have tried the various local applications, including the use of the solid "stick," and have not had sufficiently satisfactory results from any one to give it preference. The use of tonics, a generous diet and stimulants are especially indicated in these cases.

Gangrene and pyæmia call for the remedies applicable to these conditions occurring under other circumstances. Abscesses of the cellular tissue and suppurating glands should be freely opened, and are best healed from the bottom; occasionally we have succeeded in healing large abscesses by hyperdistention, afterward introducing a tent of oakum and applying firm compression. Sinuses should be laid open, otherwise they do not readily close. Balsam of Peru, in our experience, has proven more generally useful as a dressing than any other application.

We have made use of the sulphide of calcium in a number of cases selected with a view to try its efficacy in preventing the crops of boils and abscesses which so frequently follow small-pox. In no one of the cases was there any appreciable benefit from its use.

Convalescence from the severe forms of variola, and also from the milder forms, when there have been complications, is often very protracted.

Patients should not be discharged from quarantine until the whole surface is completely free from scabs and every part of the body, including the scalp, has been thoroughly and repeatedly washed. Desquamation is very slow about the elbows, knees, backs of the arms and thighs, in the palms of the hands and soles of the feet. The pustules in the hands and feet require to be opened and disinfected.

All of the clothing worn by the patient during the disease should be left at the hospital, or in cases in private practice destroyed. The bedding and other articles should be burned, not buried. No amount of washing, disinfecting, or fumigation can render them safe against infecting others.

The apartments occupied by the patient during his illness should be thoroughly fumigated with chlorine or sulphurous acid gas. The latter is preferable, because it is more easily generated. The method adopted is as follows: Close all of the windows and doors; stop all the cracks with cotton, or by pasting strips of paper over them; place a vessel containing water several inches deep in the centre of the room. In this may be floated the tin or iron vessel containing the finely broken sulphur. Moisten it with a little alcohol, which will make it burn quicker. One pound and a half of sulphur to the thousand cubic feet of space will be sufficient. The better plan is to burn a sufficient quantity to exhaust the oxygen of the room, which should be kept closed for not less than twelve hours. The windows and doors may then be opened and free ventilation permitted. After this the floors and all woodwork, including furniture, should be thoroughly scrubbed with soft-soap and hot water, to which carbolic acid has been added (one pint of cresylic or crude acid to three or four gallons of water). The walls should be scraped and freshly whitewashed or painted. The apartments from which patients suffering from small-pox have been removed to hospital should be thoroughly fumigated and disinfected. If the disease has reached the latter stages, suppurative or desquamative, all clothing and bedding used by the patient should be taken with him.

In country places or small towns, in times of epidemics of small-pox, cheaply constructed buildings are generally erected to be used as hospitals. When the disease has disappeared these should be burned and not allowed to remain standing, deserted, to afford shelter to some tramp, who, after sleeping in the infected rooms, will, in all probability, carry contagion away with him and spread it abroad.

Prophylaxis, or the preventive treatment of small-pox, is to the general public of more importance than the treatment of one or more isolated cases. The only sure method of prevention is by vaccination and revaccination at the proper intervals. Unfortunately, the conclusions first reached and published to the world by Jenner, "that one successful vaccination afforded protection to the individual for the remainder of his life," has not been entirely eradicated from the minds of many of those who submit to vaccination in the first instance, and fail to recognize the fact that, after the lapse of time, a new susceptibility to the poison is acquired. Even in this late day we frequently meet with persons who retain these views, and only submit to a second operation after much persuasion. In the country, nothing but the appearance of the dread disease in their midst is sufficient to awaken the people to the necessity of vaccination and revaccination. This disregard of so vital a matter furnishes the grounds for the strongest argument in the hands of the few anti-vaccinationists which they possess against vaccination, namely, that in spite of the practice of vaccination and the boasted immunity afforded by it, every three to five years witnesses epidemics of small-pox sweeping over the whole inhabited world.

That this does occur we cannot deny; but the explanation is easily given. An epidemic of small-pox only ceases when the material upon which it feeds is exhausted by systematic vaccination and revaccination. As soon as many communities are rid of the scourge they cease to avail themselves of the protection so easily obtained. Children are being continually born, and those who have heretofore been protected have by the lapse of time acquired a new susceptibility, and the material awaits but the importation of the contagious principle to renew the experience of former years.

Non-vaccinated children of five years and under contributed over forty per cent. of the deaths from small-pox at the hospital during the epidemic of the last two years. And while a vaccination performed in childhood may and generally does modify an attack of variola occurring in after life, so that there is little or no danger to life, it does not prevent the person infected from being the source of contagion, and increasing the number of cases, and thus indirectly the death-rate. When the day arrives at which every man shall consider it his moral duty to his children, to himself, and to the community in which he lives to pay strict attention to this great preventive measure, we shall see the world rid of this scourge and small-pox numbered among the plagues of the past.

Much discredit is brought upon vaccination by the improper performance of the operation, which is often considered too insignificant to be worthy of much care or time. The simple scarification and application of the quill is to the observer unattended with any special requirements of skill, but it is far otherwise. Nothing but strict attention to the minutiae of the operation, and close observation of the changes which occur at the spot where the virus has been introduced, and an acquaintance with the appearance of a characteristic vaccine sore will justify any one in pronouncing that the individual is thoroughly protected against small-pox. Too many of the laity are impressed with the belief that they are not only capable of performing so trivial an operation as well as the physician himself, but also that they know what a sore arm is; and this, even though they go to the doctor to be vaccinated, leads them to neglect to return at the proper time to see whether the operation is successful or not.

The careful, conscientious physician should not only

see that the operation is properly done in every respect, but what the result has been, and not rely upon the statement of the parent or any other incompetent observer as to the success. We have often been told by patients "that their vaccination had taken," when an examination showed an irritated, slightly inflamed spot, or the raspberry-looking growth which frequently occurs but is of a fungous nature, not in the least protective.

It is always advisable to procure virus, either bovine quills, or crusts one remove from some creditable source, rather than to trust to any of the patent cones, etc., guaranteed never to fail. If the quill slips can be procured fresh, they are preferable, as being most convenient, and not open to that popular prejudice of conveying disease which is held against humanized virus.

The proper age for vaccination is when the child is two or three months of age; it will then have sufficient time to recover from the effects of the operation before dentition begins. If the child be suffering from any of the acute exanthema, the operation should not be undertaken, for in all probability it will be unsuccessful. If small-pox be prevalent there can be no reasons why the operation should not be performed.

The best instrument for the operation is the ordinary thumb lancet; it is convenient, easily kept clean, and occasions less pain than any of the patent devices. The best method of performing the operation is to make a number of parallel scratches and cross these till a spot about the size of a ten-cent piece, over the insertion of the left deltoid muscle, is obtained; they should be barely deep enough to cause the transudation of serum, or the smallest possible amount of blood; the convex surface of the square cut end of the quill should then be rubbed on this surface for the space of half a minute to a minute. It is unnecessary to moisten the quill. The arm should be kept uncovered until it is perfectly dry. It is not necessary to apply adhesive plaster, or tie anything around the arm. In remote towns or country places it is often impossible to procure fresh reliable bovine virus, and it is necessary to use crusts of humanized virus instead. A portion of the crust, sufficient for the number of vaccinations to be performed, should be rubbed up on a glass slide, with sufficient water or, better, glycerine, to make a paste, which is then to be applied to the scarified surface.

On the third day after vaccination papules make their appearance at the point where the virus was inserted; these develop and by the fifth day become vesicles, which umbilicate and contain clear lymph. On the eighth day the vesicles are fully distended, and a faint blush makes its appearance around the circumference; on the ninth the areola is fully established, and is generally from the size of a trade dollar to three or four inches in diameter. There is usually some febrile action, with headache, pains in the back, perhaps nausea, and considerable itching of the arm. In this stage the vesicles should be protected by some lightly applied dressing, as vaseline applied cold on a soft old handkerchief tied loosely about the arm. Woollen or tight sleeves should be avoided. The contents of the vesicles become purulent on the ninth or tenth day; desiccation and desquamation follow, and at the end of about three weeks the whole course is complete.

Now and then we have seen patients, generally children, admitted to the hospital with small-pox, who presented a vaccination advanced to the vesicular stage and there arrested by the development of small-pox. Such cases usually pursue a modified course and recover.

Vaccination to be protective must have reached the areolar stage before the first symptoms of small-pox appear, and it does no good whatever to vaccinate persons after the symptoms of the stage of invasion have made their appearance. Since the exact time at which the contagion of variola is received cannot be positively known, as long as persons who have been exposed are well it is right to vaccinate and revaccinate them. As

has been stated, after the poison of small-pox has been taken into the system, there is a period of twelve days before any symptoms of illness are manifested. The areola of vaccination (the sign of protection), is not fully developed until the ninth or tenth day, in those who have never been vaccinated before, so that unless there is sufficient time for the formation of the areola before the first symptoms of small-pox are manifest there will be no benefit from vaccination. If a person receive the poison of small-pox on Monday and be vaccinated two days later it will be in time to prevent the development of that disease; if vaccination be done on the third day small-pox will appear but will be modified; if the vaccination be postponed beyond the third day no benefit will be received, since there will not be time enough for the development of the areola before the first symptoms of small-pox appear. In secondary, or revaccination, the areola appears on the seventh or eighth day, therefore vaccination will be protective if done two days later.

ON THE

OCCURRENCE OF THE BACILLUS TUBERCULOSIS IN TUBERCULOUS LESIONS.

By T. MITCHELL PRUDDEN, M.D.,

NEW YORK.

DIRECTOR OF THE PHYSIOLOGICAL AND PATHOLOGICAL LABORATORY OF THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, N. Y.; LECTURER ON NORMAL HISTOLOGY IN THE YALE MEDICAL COLLEGE.

A CAREFUL and impartial study of Dr. Koch's papers on the bacillus tuberculosis, and the more or less valuable communications upon the same subject which have followed in great numbers, would seem to lead to the conclusion that an important discovery has been made; although how important, and in exactly what direction its value lies it is yet too early to say. The incomparable mortality of tuberculosis, the almost boundless possibilities in prophylaxis and therapeutics which the establishment of the new hypothesis suggests, and the generous hospitality which is to-day so freely accorded both by lay and professional writers to all so-called germs, have combined to give to this bacillus an importance which only a much more extended series of careful observations can fully justify. In the prevailing furor it is important to remember that even if all that is claimed for the new bacillus should be proven true, still the morphological basis upon which the present knowledge of tuberculosis rests has not been in the least disturbed, and that even the proof that this bacterium causes all the lesions of tuberculosis, would not explain either the peculiar reaction of the living organism against the parasite or the varied phenomena of the distribution of tubercle, heredity, variations in mode of attack, etc. While, however, a too ready acceptance of the new belief is to be deplored, it should not be forgotten that such a carefully conducted series of experiments as that by which Dr. Koch was led to his conclusions, is not to be met or shaken either by general scepticism or by reasoning based on analogy or more or less remote clinical data. It is only by actual experiments and observations, as minute, extended, and logical as his own, that Dr. Koch's conclusions are to be confirmed or disproved.

The proof of the parasitic character of any infectious disease involves, first, the demonstration of the constant association of the parasite with the disease—this may be called the morphological part of the problem, and is often mistakenly regarded as the most important; second, the complete isolation of the parasite by cultivation; third, the production of the disease in a healthy animal by inoculation; fourth, and lastly—and this factor is, unfortunately, too generally ignored—it is necessary, in order to make the results of animal inoculation applicable to man, to prove that his organism will react in approximately the same way in the presence of the parasite as the animals experimented on.

The present paper, which has almost exclusively to do with the first or morphological part of the problem, presents the record of the examination of a series of cases of tuberculosis with a view of determining to what extent, and in what way the tubercle bacillus was associated with the lesions in the material at the writer's disposal. The results seem worthy of record, not because of any novelty either in method or result, but simply because they serve to increase the data available for arriving at just conclusions upon the important subject of the etiology of tuberculosis. The simple purpose of this paper and the contemporaneous character of the publications on the subject, will justify the absence here of specific reference to the work of other observers.

It requires but a short practical experience in the staining and study of phthisical sputum and tuberculous lesions to become convinced that they are more or less constantly associated with a well-defined bacterium, having the characters described by Dr. Koch. It is highly important, however, to determine at the outset very definitely the exact distribution of the bacillus in tuberculous organs, and whether they are present in every growth of tubercle tissue, for simply to say that the parasite may be found in the sputum, or in the organs of all cases of tuberculosis examined, means little unless the number of cases is recorded and the seat of the parasite described. For, as has already been shown, and as will be seen farther on, they have a marked predilection for certain parts of the body or organs, and for certain varieties of the lesion; all of which has an important bearing upon the significance which we must ascribe to their presence.

It has been the writer's endeavor, in the present series of examinations, to hold himself strictly to the morphological phase of the problem, and not to permit the observations to be in the least prejudiced by the cultivation and inoculation experiments thus far done and recorded by others.

Technique.—The method of staining employed was Ehrlich's, which, in the writer's experience, gives uniform and satisfactory results. The staining fluid was warmed to about 50° C. when the specimens were immersed, and the staining prolonged to twelve hours. The most scrupulous attention was given to cleanliness of instruments and apparatus, in order to avoid contamination of specimens from previous examinations. Here, as everywhere in delicate technical procedures, and here perhaps to an unusual degree, a certain amount of experience is requisite in arriving at precision of result; and accordingly a long series of the earlier examinations are not included in the present record, except those upon material capable of re-examination. The Abbé condenser was made use of, and greatly facilitates the examination, although in many objects—sputum, for example—it is not absolutely indispensable.

Sputum was prepared in the usual way, and, after staining and decolorizing, the specimens were mounted in glycerine, in which the bacilli appear with perfect distinctness, and retain the color for several weeks; the recorded examinations were, however, made immediately after the staining. In the examination of tissues the method varies, depending upon the exact purpose of the study—whether for the simple determination of the presence or absence of the bacilli, or for their exact location in the tissue. If for the former purpose, a fragment, a miliary tubercle, for example, may be picked out, moistened with a minimum quantity of distilled water, and ground to a pulp in a small mortar, and the pulp applied to the cover-glass and treated as in the manipulation of sputum. This method is valuable, because it enables the observer to obtain an approximately accurate analysis of the contents of an entire miliary tubercle or other small nodule; but it is especially applicable to fresh tissue, and is obviously less exact for the purpose of localization than the examination of thin sections. Sections may be cut from the fresh tissue by the freezing microtome, but in the present studies they were cut by

the ordinary microtome from tissues hardened in strong alcohol. Thoma's microtome was used, and the sections were cut of a nearly uniform thickness of .01 mm. After staining and decolorizing, the sections were mounted and studied in oil of cloves, in which the color is perfectly preserved for several weeks, and often much longer. It is important that tissues be hardened in alcohol, and only specimens thus preserved were used. Organs whose blood-vessels are injected with acidified coloring material are not available, since the bacilli under these conditions do not uniformly stain. Organs which have become partially rotten before the preservative and hardening agents are used are also useless, for the same reason.

The material examined was all from man, and may be classified as follows: 1, acute miliary tuberculosis of lung, nine cases; 2, sputum in acute and chronic phthisis, fifty-eight cases; 3, sputum in chronic bronchitis and lobar and lobular pneumonia, nine cases; 4, lung lesions in acute pneumonic phthisis, six cases; 5, lung lesions in chronic phthisis, thirteen cases; 6, miliary tubercles in liver, three cases; in kidney, two cases; in spleen, three cases; in pia mater cerebri, four cases; ependyma of lateral ventricles, two cases; 7, localized primary tubercular pleuritis, two cases; 8, tubercular ulcers of small intestine, eight cases; of larynx, one case; 9, typhoid and dysenteric ulcers of intestine, six cases; 10, primary tubercular inflammation of bladder, ureter, and kidney, one case. The importance, for purposes of control, of the examination of non-phthisical sputum and non-tubercular ulcers is obvious.

Acute miliary tuberculosis of lungs.—Nine cases. Four of the cases were uncomplicated acute general miliary tuberculosis, with miliary tubercles in lungs, liver, spleen, kidney, and pia mater cerebri. In the remaining five cases from young children the tubercles were confined to the lungs and were associated with chronic peri-bronchitis, chronic interstitial pneumonia, and bronchiectasis, but the tubercles were the predominant lesions and were presumably the cause of death. These cases were studied by 520 sections of miliary tubercles from different parts of the lungs, and by 105 entire tubercles which were ground to a pulp and stained in the manner above described. The tubercles, control sections from which were examined after staining in hæmatoxylin and eosin, presented the usual structural variation; some being of the traditional giant-celled type, others of the pneumonic form, some dense, others cheesy and disintegrating at the centre. The bacilli were found in eight of the cases, in about seventy-five per cent. of the individual tubercles examined. They were entirely absent from all of the tubercles examined in one case (180 sections and 15 entire tubercles). In the cases in which they were present, the number of the bacilli varied greatly. In some of the sections there would be twenty or thirty, in others only one or two. As a rule they were most abundant in the vicinity of the cheesy centres which were undergoing disintegration, but they were not infrequently scattered in small numbers in the intact tubercle tissue near the periphery of the nodules; more rarely in tubercles which presented no cheesy degeneration or breaking down. They were present occasionally in the giant-cells, but seemed to have no predilection for this situation; the record of examination of giant-cells showing the presence of bacilli in about one in sixty. A large number of large and small bronchi and their contents and blood-vessels, were examined but no bacilli were found in them. The case in which no bacilli were discovered was from a young child with acute general miliary tuberculosis with tubercles in lungs, liver, spleen, pia, and ependyma, the tubercles in the lungs were few in number, in the other organs moderately abundant. In a large proportion of them there was cheesy degeneration but very little breaking down. They were mostly loose in texture, containing the usual proportion of giant-cells and presented the usual variation in character in the different organs which is found in acute general miliary tuberculosis. They did not appear to differ morphologically in

any respect from the tubercles in the other cases in which an abundance of bacilli were found. As will be seen below, the bacilli were absent in this case not only from the tubercles in the lung, but also from those in the spleen, liver, kidney, pia, and ependyma of the lateral ventricles.

*Sputum in acute and chronic phthisis.*¹—The material was taken from cases in which the diagnosis had been carefully made by competent observers, and in ten cases confirmed by autopsy. The sputum was collected in carefully cleansed wide-mouth bottles, which were used for spit-cups, and in most cases embraced all that was expectorated during the night and early morning hours.

This was carefully mixed in the bottles by prolonged shaking, and in all cases several examinations were made to insure accuracy. In some of the cases giving negative results, the examinations were repeated at intervals of days and weeks. The number of cases of phthisis from which sputum was examined was 58. In these the bacilli were present in 46 cases, absent in 12. Of the 46 cases in whose sputum the bacilli were found, physical examination revealed cavities in 41. Of the 12 cases whose sputum was without bacilli only 4 had cavities; 5 of these 12 cases passed from under observation before re-examination was made, 2 died before re-examination, and no autopsy was made. At the autopsy of one of the negative cases which died shortly after the examination of the sputum, no cavities were found, but myriads of bacilli were found embedded in dense cheesy nodules in the lungs. The remaining negative cases presented on physical examination a moderate amount of consolidation, but no cavities.

In some cases, notably in those presenting large cavities, the bacilli were present in the sputum in enormous numbers, in others they were not very abundant. To this general rule, however, there were occasional exceptions, for in some cases with numerous and extensive cavities the number of bacilli was small and remained so up to the time of death.

The presence of spores within the bacilli was observed with varying frequency in nearly all cases, and the abundance of these forms appeared to bear no definite relation to the size of the cavities or the gravity of the disease. They were as often found in the sputum of patients with small cavities, who were not apparently very sick, as in that of those in the last stages of the disease.

Sputum in chronic bronchitis and lobar and lobular pneumonia.—The examination of sputum from six cases of chronic bronchitis, two cases of lobar pneumonia, and one case of lobular pneumonia gave negative results, no bacilli were found.

Acute pneumonic phthisis.—The number of cases examined was six, and the bacilli were found in all. In all but one of these cases there were several cavities, some large and some small, and in the contents and in the inner disintegrated portions of the walls of all of the cavities there were large numbers of bacilli. In cases in which there was a distinct wall to the cavity, the bacilli were absent in the outer portion of the wall adjoining the lung-tissue. In the consolidated areas of the lungs—one hundred and forty-nine sections from various parts—the bacilli were present in great numbers, in a large proportion of instances where the cheesy portions were breaking down, and in a few instances they were present in the cheesy masses which were still dense and solid. In one case they were scattered in and among the cells in air-vesicles lying in the periphery of tuberculous nodules, which contained otherwise only the exudations of simple pneumonia. In nodules composed of tubercle tissue which was not cheesy, the bacilli were present in many but not all cases, but always in small numbers.

Chronic phthisis.—Number of cases, thirteen. In nine of these cases there were larger and smaller cavities. In

¹ The writer wishes to express his sincere thanks to Dr. H. Koplik, Resident Physician to Bellevue Hospital; to Dr. W. T. Van Vredenburgh, Resident Physician to Roosevelt Hospital; to Dr. W. S. Gottheil, Resident Physician to Charity Hospital, and to Dr. C. S. Mack, First Assistant Resident Physician to Mount Sinai Hospital, for their courtesy in securing the collection of material for this part of the investigation.

the lungs, in which, without or in addition to cavities, there were larger and smaller consolidated areas, these presented the usual variation in structure, which it is not necessary to describe in detail. In all of these cases of chronic phthisis, the bacilli were found, usually in large numbers. In four of the cases they were met with only in the walls and contents of cavities and in the contents of the bronchi. Eighteen cavities were examined, and in all the bacilli were found in enormous numbers, many of the yellowish masses clinging to the walls consisting almost entirely of them. In cases in which the cavities were limited by a distinct wall, the bacilli were usually found in the inner portion only. In the consolidated tuberculous areas, of various forms—four hundred and sixty sections from different parts of the lungs—the bacilli were found in a small proportion only, and in these, with few exceptions, only in and immediately around cheesy areas which were disintegrating. In a few instances they were found in large numbers in dense cheesy areas, and, in a few instances, in the intact diffuse tubercle-tissue in the periphery of the cheesy nodules. In one lung they were found in considerable numbers in the air-vesicles near tuberculous nodules, which contained otherwise only the ordinary products of simple inflammation. They were never found in areas of simple intra-alveolar and interstitial pneumonia, except when these were closely associated with tubercle tissue. They were found in considerable numbers, in large and small bronchi, in cases with cavities; in others they were invariably absent. The inner walls and contents of a large number of blood-vessels were examined, but no bacilli were found. It will thus be seen that in the cases of chronic phthisis examined the bacilli were found in all, but chiefly in the walls and contents of cavities and in and about cheesy areas; most frequently in such as were disintegrating, but occasionally in those which were not. Their occurrence in diffuse tubercle tissue not cheesy was comparatively infrequent, and in the dense so-called fibrous tubercles they were never found. Their presence in the giant-cells of all forms of the tuberculous lesions in chronic phthisis was infrequent.

Miliary tubercles.—In kidney, two cases; spleen, three cases; liver, three cases; pia mater cerebri, four cases; ependyma of lateral ventricles, two cases. These organs were all from cases dying with acute general miliary tuberculosis. In the tubercles of one of each of the different organs—those from the above-described case, in which no bacilli were found in the lung tubercles—no bacilli could be detected, although about one hundred and fifty sections from different tubercles were examined, and a large number examined entire after grinding to a pulp. In all of the remaining cases bacilli were found. When present, they were very few in number, and were as often present in tubercles without as in those with cheesy degeneration. Very rarely were more than two or three seen in a single section of .01 mm. in thickness, and never the large clustered masses so frequent in the lungs.

Localized primary tubercular pleuritis.—Two cases. The tubercles in these cases were of the loose-textured, traditional giant-celled form ("Schüppel's tubercles"), with and without cheesy degeneration. The bacilli were found in both cases in a large proportion of the miliary tubercles, but always in small numbers.

Tubercular ulcers of intestine.—Nine cases. Larynx, one case. These were all from cases of chronic phthisis. In eight of the cases with intestinal ulcers, the bacilli were present in all of the ulcers examined, but in comparatively small numbers. They were scattered in and among the shreds of necrotic tissue at the bottom and sides of the ulcers and in the tubercle tissue in the vicinity. In one case they could not be found. In this case thirty sections from six different ulcers and scrapings from portions of these and from two others were examined with the greatest care. As shown by the examination of sections stained in the usual way, the ulcers in this case

were typically tubercular in character. The lung in this case had not been saved, so that it is not known whether the bacilli were present in it or not. In the ulcer from the larynx, which was shallow, they were present in small numbers in all of the sections.

Typhoid ulcers, two cases; dysenteric ulcers, four cases. The examination of these ulcers for purposes of control gave entirely negative results, no tubercle bacilli being found.

Primary tubercular inflammation of bladder, ureter, and kidney.—One case. The lesions in this case were seen both macroscopically and by the study of sections stained with hæmatoxylin and eosin to be of most unmistakable tubercular character, and yet the examination of a large number of sections from different typical parts and of a number of scrapings, and of the fresh purulent fluid abundant in the calices of the kidneys, failed to reveal a single tubercle bacillus.

In reviewing the above recorded studies, it will be seen that in 100 cases of tuberculosis of various forms, in none of which the diagnosis was doubtful, and in 51 confirmed by autopsy and thorough subsequent microscopical study, the examination for the presence of bacilli in nearly 1700 preparations revealed their presence in 46 out of the 58 cases of simple sputum examinations and in all but 3 of the 42 cases whose tissues were examined after death.¹ In one of the three exceptional cases, however, the examination was only partial, being limited to ulcers of the small intestine in a case of chronic phthisis. Again, in a large proportion of the cases in which they were present they seemed to have a decided predilection for tubercle tissue in a degenerated and disintegrating condition, either cavities in the lungs, cheesy and breaking down areas or tubercular ulcers, although present with great frequency in small numbers in well-formed intact tubercle tissue. In the present series of cases it is worthy of remark that the bacilli were present in far greater abundance in the respiratory organs and intestinal tract than in other parts of the body less directly in communication with the external world.

It is further evident that in nearly every case there are many miliary tubercles of all forms, and in many cases much diffuse tubercle tissue, from which the bacilli appear to be entirely absent.

The examination of the present series of sputum of phthisis throws but little light upon the value of such study for diagnostic purposes, since in most of the cases the diagnosis was certain enough without recourse to this factor. While undoubtedly the detection of bacilli in sputum in doubtful cases may be of great value in forming a diagnosis, it should be remembered that their absence does not exclude the possibility of the existence of phthisis. This is shown in one of the above cases, in which careful examinations of sputum failed to reveal bacilli, and yet on the death of the patient both lungs were extensively involved and large numbers of bacilli were found embedded in cheesy nodules; *but there was little breaking down of tubercles and no cavities.* The abundance of bacilli and the presence of spores within them does not seem to the writer to have the importance in the formation of a prognosis which has been ascribed by some recent writers to them, since the presence of large numbers of the spored forms was observed in all classes of cases, and in many of the gravest cases the bacilli were present for long periods in comparatively small numbers.

In regard to the miliary tubercles and other forms of tuberculous tissue in which no bacilli could be detected, although they were found in other parts of the body, and also to those cases in which, although distinctly tuberculous, no bacilli were found in any part of the body, the simplest conclusion would be that they were not there. But to the unqualified adoption of this conclusion those

¹ The apparent discrepancy between the figures in this summary and those in a preceding portion of the paper are due to the fact that in the former arrangement of the material by organs several of the specimens belonged to one case.

objections may be justly urged. In the first place, it should be remembered that our main reliance for the detection of the bacilli is upon their staining, but, as recognized by Dr. Koch in his first article upon this subject, they may, when life in them is becoming or has become extinct, fail to stain and hence escape detection. Dr. Koch furthermore recognizes the fact that they may be entirely absent from some forms of tubercle tissue, but assumes that this is the case only when the tuberculous process has come to a standstill. It does not, however, seem to the writer that we are sufficiently familiar with the process of development of all forms of tubercle tissue to enable us to say in many cases positively, or even with great probability, which tubercles are in an early and active stage of development and which are not; hence it is very difficult to form a definite conception on morphological grounds of the part which the bacilli play, if any, in producing tubercle tissue. This difficulty of determining the exact significance of the presence of small numbers of or of single bacilli in or near tuberculous lesions is enhanced by the possibility that they, like pigment or other small granules, may be carried about passively to a certain extent through the lung tissue by amoeboid cells or lymph currents. The failure of the bacilli to stain under certain conditions has been repeatedly observed by the writer in the walls and contents of cavities and sputum, which when fresh showed an abundance of easily stained bacilli, but in which after being allowed to remain in a warm, moist atmosphere until a considerable degree of decomposition had occurred, the bacilli could be detected only with the greatest difficulty, being in a few cases but very slightly and in most not at all stained.

Again, the results obtained by the above methods, sections and grinding of entire tubercles, do not admit of absolute accuracy, since the bacilli are very small, and it is obviously impossible to examine completely all of the tuberculous lesions in any given case, the degree of approximation to absolute accuracy depending entirely upon the thoroughness of the work. The objection, that in all this morphological work on the distribution and occurrence of the bacilli in tuberculous lesions there is a certain lack of precision, seems to the writer to be a perfectly sound and legitimate one. The lack of absoluteness in the data upon which conclusions rest is one of the evils inherent in every incompletely developed science, and particularly in the medical department of the science of biology, and the frank recognition of this inherent difficulty in many of our problems would leave our conclusions quite as available for future use if proven true, and much less difficult to get rid of if false, than if we ignore it. Nevertheless the limitations in the present case are so clearly defined that the acknowledged lack of absolute precision would seem to be of no vital importance in the present phase of the inquiry.

It should not be forgotten that it is a form of inflammation with which we are dealing in tuberculosis, the characters of which are by no means embraced by the traditional descriptions of miliary tubercles, descriptions whose very precision and exclusiveness have unfortunately come to be stumbling-blocks in the way of progress toward a broader comprehension of the entire process. It does not appear at present that there is such unity in the lesions of tuberculosis as to render improbable a duality of causation.

The writer is perfectly aware that the discussion of the causation of tubercular inflammation from the morphological standpoint alone can never be aught but an imperfect and partial one; but the demonstration, with the above limitations, of the fact that tubercular lesions can exist without the presence of the tubercle bacillus in them, while not in the least tending to discredit the possibility, or even the demonstration by Dr. Koch of the bacterial origin of many or most forms of tuberculous lesions, would seem to make the doubt of its universality perfectly legitimate. It should be remembered, finally, that Dr. Koch's experiments have not been done on man,

but on the lower animals, and that the proof that the human organism reacts toward the bacilli in the same manner as that of other species has not yet been furnished, and in the absence of this link, the facts recently furnished by Schottelius¹ in regard to the harmlessness of the ingestion of presumably tuberculous meat by man, and what is still more important, the large amount of clinical experience which at present seems distinctly not in harmony with the new hypothesis, should receive careful consideration.

TRIAL BY JURY.

AS A MEANS OF ASCERTAINING THE MENTAL STATE OF ALLEGED LUNATICS, AND AS A PRE-REQUISITE TO THE SECLUSION OF LUNATICS.

By RALPH L. PARSONS, M.D.,

GREENMONT-ON-THE-HUDSON, N. Y.

A BILL has recently been introduced in the New York Legislature, or is about to be introduced, providing that hereafter no person shall be deprived of his liberty in this State, as a lunatic, unless such person shall have been duly tried on the charge before a jury of his peers, and shall by them have been adjudged insane. The objections to such a law are so grave that the probabilities of the measure being approved by this or any other legislature would seem to be slight. Yet its advocates are earnest and undoubtedly sincere in the belief that such a law is required; and it must be remembered that earnest, sincere men often accomplish their ends against truth and justice and against the feeble efforts of indifferent opponents. In fact, this has already taken place in the State of Illinois, where a similar law has been in existence for some years past. Hence the subject is of sufficient importance to entitle it to general attention and especially to the attention of physicians.

The following are the most important of the considerations urged in favor of the proposed law.

In the first place the general plea is urged that it is both unconstitutional and is a dangerous invasion on the rights and liberties of the citizen to incarcerate him without affording the opportunity of making a defence in accordance with the usual legal forms. Every citizen is entitled to the rights and benefits of a trial by jury before he can justly be deprived of his liberty under any pretence or charge whatever, and a violation of this right involves possible danger to every citizen. It does not follow even that every man who is of unsound mind is dangerous to the community and ought to be placed in prison. But physicians are educated to look upon all lunatics as subjects of a dangerous disease and to think that the only proper course to take with them is to shut them up. As the law and the practice now stand, the doctor is, to all intents and purposes, both judge and jury in the case. An ordinary jury is quite as competent to judge of the weight of evidence in a case of alleged lunacy as in any other brought before them for judgment, and is more likely to decide without bias than medical men are.

It is further urged that through defects in the present methods of adjudging men to be insane many are actually incarcerated as lunatics who are of perfectly sound mind; and that if a trial by jury were required in all such cases this danger would be for the most part if not altogether avoided.

Some of these reasons and arguments are plausible but it is believed that none of them will bear the test of a candid examination. A man's house may be pulled down or his property destroyed without process of law if by reason of a conflagration or of any great public danger it becomes a public menace. Or a person sick of a dangerous, contagious disease may be removed from a hotel or public building on the simple judgment and

¹ Virchow's Archiv, Bd. 91, Heft. 1, S. 120.

authority of one or two men who are assumed to know the nature of the disease. And sometimes mistakes are made in both these instances. But the public have rights as well as the individual. So in the case of lunatics, they may justly be restrained without any process of law, if the public safety or even if the safety of the insane person demands. Further than this due process of law is and always has been required. But the assumption that a jury would make a better judgment regarding the question of sanity in a given case than is now made by the methods in ordinary use, either in this country or abroad, is altogether gratuitous and improbable. The main weight of the evidence that would be brought before a jury would be the *opinion* of the physicians who had made a study of the case, and if such opinions did not prevail with them as determining facts the presumption would certainly be against the jury and in favor of the scientific decision of the physicians.

It is quite true that from time to time mistakes are made in the diagnosis of insanity, and that sane men are deprived of their liberty under such a mistaken diagnosis. Indeed, it would be strange if mistakes were not sometimes made in this as well as in other matters upon which men form candid deliberate judgments. But it should be remembered that there may be vast differences in the character of the mistakes that are made. For instance, a mistaken diagnosis of insanity might be founded on eccentricities of conduct that were an expression of the natural characteristics of the individual and were harmless in character; or, a mistaken diagnosis might be founded upon such appearances, actions, and language as are usually found to be the expression of a state of lunacy. In the former case, a more careful investigation would have served to establish the true nature of the case. As a matter of fact, this sort of mistake is of very rare occurrence. In the latter case, or rather class of cases, for the manifestations are very diverse, the person suffers no serious harm on account of having been judged in accordance with his actions. At all events, it is in the highest degree improbable that a jury would have made a more correct, or even a different judgment. Almost without exception the *improper subjects* who have come under my own observation, have been of this category. They have been cases of delirium, of cerebral congestion, of concussion, of alcoholism, of drug-poisoning, or of pure folly, or malignity of disposition that has been brought to the surface by some peculiar train of circumstances. The following example will serve to illustrate the last-mentioned type: A married man with a family of grown-up daughters, is observed by his family physician to conduct himself in a strange excited way, to run excitedly about the street, hatless, with dishevelled hair and disordered garments, to talk in an excited way, to neglect his business, and to disturb the quietude of his household. He mentions the subject to the family and is informed that the husband and father watches about the house in corners and by-places as though he suspected some conspiracy, and that he is at times so violent in language and conduct that the family fear lest he may do some of them bodily harm; in fact, that one day he actually did seize one of the smaller children in a violent manner and hold it over the heated range. The physician made the diagnosis of insanity, and advised commitment to a lunatic asylum as a measure of safety. It afterward transpired that the alleged lunatic had an ungoverned and ungovernable temper, that during the whole twenty years of his married life he had been subject to outbreaks of blind passion whenever his wishes were opposed, and that latterly the malignity of his disposition had been brought out with especial virulence by a series of family events, among which were a growing indisposition on the part of his daughters to submit to his abusive language and treatment, and the advent of a lover to one of the daughters he did not approve. He was found not to be insane, and collected damages of the family physician for false

imprisonment. The physician was, without doubt, entirely honest in his diagnosis. The members of the family were quite willing to accept his view as a plausible explanation of the father's conduct, and as a means of relieving them of such a terror, and so were not anxious to change the doctor's opinion. Few will be likely to think, however, on a careful consideration of the circumstances, that the doctor ought to have been fined on account of his mistaken diagnosis, or that the father did not deserve to be considered a lunatic and treated like one, since his conduct had fairly entitled him to that distinction. In the other cases to which reference was made there was a state of actual mental obscurcation, although the condition was not one of technical insanity. The patients—for such they should be considered—needed treatment somewhere, and might possibly have done worse than become inmates of a lunatic asylum.

The impression, which would seem to have gained some credence, to the effect that large numbers of sane persons are shut up in lunatic asylums, is strengthened by the various suits at law which are brought under this pretence or belief. Yet it will undoubtedly be found that very few persons of this class who have been declared of sound mind by an intelligent jury, in opposition to the opinion of well-educated physicians, really conducted themselves so rationally as to inspire universal confidence in their sanity.

The statement that sane persons are often shut up as insane through interested motives is rarely made. The supposed instances are not numerous enough nor clear enough for that. The claim is rather that sane persons *may* be put in asylums through such motives. Certainly every sort of injustice is possible, but the obstacles to the perpetration of this sort of injustice are too great to render the attempt attractive. Too many persons of responsible position would require to be in guilty collusion in the first instance; and the dangers of detection by numerous other persons would be too imminent.

The fact is that the ratio of indisputably sane men who are incarcerated in asylums as insane is so small that the Lunacy law should be constructed with especial reference to the welfare and interests of our unfortunate fellow-citizens who are really insane. While the legal methods should be such as to prevent mistakes as far as possible, they should be so ordered that the insane may enjoy every needed facility to get that early efficient care and treatment which their malady requires.

A trial by jury would be very decidedly prejudicial to the interests and welfare of many, if not of a majority of the insane. The whole process of being arraigned and tried before a court on any charge is repugnant to most men. The charge of being insane is particularly offensive, especially when made in public, and no less so to many of the insane than to those who are of sound mind. Not only would such a trial be offensive to many of the insane, but it would also be repugnant to all of their devoted friends. The inevitable result would be that friends would hesitate and delay in taking the necessary steps for early and efficient management and treatment. It is a well-established fact that the likelihood of recovery depends very much on the promptitude with which the patient is removed from perturbing influences, placed in favorable surroundings, and properly treated and managed. Although the hesitancy of friends to subject the unfortunate patient and themselves to the repulsive ordeal of a trial would probably be the most important cause of delay, there must be added to this the various causes of delay that would of necessity be incident to the trial itself.

The following quotation from the Annual Report for 1882, of Dr. H. F. Carröl, Medical Superintendent of the Asylum for the Insane, at Jacksonville, Ill., will show that the above-mentioned objections are not merely hypothetical, but are supported by actual experience, viz.: "It is probably in the experience of every superintendent in this State (Illinois), as it certainly has been

in mine, to notice how many have been deterred from making application for their friends' admission to a hospital on account of the laws of this State requiring a public trial, a judge, jury, and lawyers, just as in a criminal proceeding. I say many are kept out of the hospital in the early stage of the disease on account of the repugnance and dislike in the minds of friends to this public trial. Many such cases have come under my personal notice."

Again, the immediate effect of a jury trial, or of any proceeding analogous to a jury trial, would be highly prejudicial to many of the insane. It may be admitted that cases often occur that might not be seriously injured by a trial, as those which are apathetic or demented; but these are not the cases for which the formalities of a trial would be invoked. The process would of necessity be a serious cause of disturbance and injury to all insane patients who were able to comprehend the nature of the proceedings and of the evidence.

In addition to the disturbing influence of the proceedings themselves, they would be disturbed, annoyed, and injured by the evidence adduced in proof of their insanity. They either deny the truth of such evidence or do not admit the inferences that are drawn. In either case they naturally feel that they are objects of misrepresentation and injustice.

A consideration of the actual facts and circumstances attending cases of insanity will show more clearly than any merely theoretical discussion how annoying and harmful a jury trial would be.

For instance: a young girl suffers an attack of melancholia attended by morbid fears and suspicions, or from an accession of hysterical mania with nymphomaniacal propensities. In the former case she shrinks from strangers with terror, and in the latter she behaves in an unbecoming manner in their presence. Or the mother suffers from an acute attack of puerperal mania attended at the same time with great mental disturbance and great physical depression. Her immediate safety requires that she be carefully protected from all disturbing influences and promptly placed under the conditions most favorable for efficient care and treatment. Or the father suddenly manifests symptoms of mental aberration, which it is hoped will be only temporary in character, but whose case requires prompt and careful management. It may safely be assumed that even the most strenuous theoretical advocate of the jury trial would hesitate a long time before subjecting a dear relative or friend who was suffering as in the cases instanced above, or in a multitude of similar ways, to the coarse, repulsive ordeal of such a trial. They would be restrained by their own better feelings; by a humane wish to protect the sufferer from unnecessary annoyance, pain, and danger, and by a desire as much as possible to avoid a publicity which might seriously prejudice the social or business interests of the patient after recovery had taken place, and the remembrance of which would certainly be a painful one. Harmful delay in taking the measures most conducive to the welfare of the patient would be the probable result.

Even in the case of a patient suffering under a mild form of mental aberration without serious physical disturbance, and who is anxious for the trial, such a procedure is by no means certain to be harmless to the patient. He will certainly not be convinced of his insanity if a dozen juries were to pronounce him insane. It is not unlikely that he will be irritated by the appearance against him of those whom he supposed to be his friends, and that he will be annoyed by evidence which appears to him irrelevant or untrue, or distorted, and that diminished prospects of recovery will be the result. The influence upon such a patient will be more especially bad when, as is often likely to happen, there is conflicting evidence and conflicting opinions are expressed. Being of an argumentative disposition of mind, he will afterward urge the evidence and opinions in fa-

vor of his sanity as true and correct, and thus establish himself in his insane delusions, although the decision may have been adverse to his sanity.

The conclusion is that men who manifest no symptoms indicative of insanity need have little fear of being shut up in lunatic asylums as insane; that if possibly mistakes are sometimes made in the case of some who appear and act in a greater or less degree as though they were insane, the results are not likely to be very serious in character, and that the injury of a jury trial to the insane as a test of their sanity would immensely counterbalance any possible advantages that might accrue to the sane. The insane are the weaker parties, and need the full protection of the laws, in this instance by being protected from legal annoyances. If a few sane men and women are in danger of being declared lunatics, means certainly can be devised for their protection that will not be prejudicial to the multitudes of the insane.

If additional means not prejudicial to the insane can be devised to prevent such mistakes as are liable to occur, and it is altogether probable that the methods of investigation and procedure can be improved, there will certainly be universal and unqualified acquiescence in such improved methods.

THE ANALOGY BETWEEN UNION IN SCION-GRAFTING AND THE HEALING PROCESS OF WOUNDS.

By H. I. RAYMOND, M.D.,

ASSISTANT SURGEON U. S. ARMY.

THE surgeon is satisfied to consider a wound aseptic that fulfils these two conditions, viz., emits a sweet, healthful, non-putrefactive odor, and reveals to the microscope no micro-organisms upon the wound-surface. When antiseptic surgery was first introduced to the profession, surgeons observed that under the use of certain so-called antiseptics, a wound would run an aseptic course, but not apprehending clearly the rationale of such action of an antiseptic, experiments were set on foot by investigators to determine the same.

One of the most recent and plausible explanations of how an "antiseptic" provides for the two conditions mentioned above, as essential to an aseptic course, is that set forth by Boillet in his experiments with zinc chloride and carbolic acid. Although his experiments are familiar to the medical world, I desire to recite them in brief in this paper, in order that the theory which Boillet advances as to why zinc chloride or carbolic acid secure good healing in flesh wounds may be compared with a theory—its prototype—on scion-grafting, published before 1855, and appearing in an article on "Fruit-garden" in "Chambers's Information for the People."

First, then, for Boillet's theory of the action of zinc chloride or carbolic acid upon the prevention of the development of micro-organisms upon a wounded surface. The assertion that these substances acted detrimental to bacteria, or at least arrested their growth, was shown by Koch's experiments to be incorrect. He placed certain species of micro-organisms for a longer or shorter period in one of the antiseptic media under question, and then brought them into a favorable culture medium and found that their function of development had not decreased. But although the afore-mentioned antiseptics exert no direct fatal effect upon bacteria, they do act preventive to the development of bacteria in wounds.

Now, Boillet explains that this prevention depends upon their power to form insoluble compounds with albumen. Thus chloride of zinc added to a solution of albumen, gives an insoluble albumenate of zinc; in a similar manner an albumenate of mercury may be formed with the corrosive chloride, and even carbolic acid was found to produce a precipitate in albuminous solution. A part of a solution of the albumenates of zinc, copper, and mercury in water was placed in the open air, and

another portion of the solution was supplied with the germs of bacteria. These solutions of the metal albumenates proved to be unfavorable culture media for bacterial germs. In the solution exposed to the air, bacteria did not appear until after four weeks, and after six weeks only could a decided decomposition be recognized.

In preparations of pure albumen exposed to the air, bacteria appeared very shortly after twenty-four hours. Now, according to the opinion of Boillet, these metal-albumenates would prevent the development of bacteria for an indefinite period, *if they were not decomposed by the oxygen of the air and the water.*

Now follows Rennie's theory of the treatment of scion-grafting, published nearly three decades ago. My attention was called to it in a letter from Dr. Adler of the army.

The practice advocated is that of bandaging the grafted pieces by a strip of mat, lightly applied, so as not to obstruct the circulation, and over this bandage is plastered around a handful or two of a soft adhesive material—a conglomeration of clay, cow-dung, and chopped straw. This will form a hardened coating over the junction of the coapted surfaces, and may be allowed to remain until midsummer, when, union having been perfected, the plaster case may be removed.

The principle upon which the external plaster was applied over the junction of the raw surfaces was that of *excluding the atmosphere* from the wound, and is thus scientifically explained by Rennie.

"It is to prevent the oxygen of the air from getting to the fluid pulp at the joining, where it would unite with the carbon and form carbonic acid gas, and thereby rob the pulp of its solidity. The exclusion of light is necessary on the same account; for, as in the case of a finger cut, the oxygen would unite with the carbon and prevent the thickening of the blood. On the same account, moisture by supplying oxygen would be injurious, and dryness might act both by exhausting the pulp, and by causing the edges of the bark to shrivel and to gape, which would facilitate the entrance of the air with its oxygen. It must be obvious that the occlusive covering of plaster conferred a benefit by its virtue of excluding the atmosphere, for the principle (never, so far as I am aware of, before stated in reference to scion-grafting) that no composition, whatever may be said of its peculiar power of healing, can act in any other way than this, any more than the farrago of plasters and salves for healing flesh wounds and cuts, which are only good in so far as they keep the lips of the wound together *and exclude oxygen and light.*"

Rennie wrote this in 1855. Is not his theory of scion-grafting a prototype—in analogy—of the recent theory of Boillet that explains the reason why flesh wounds heal favorably under an impermeable albumenate formed by the union of a metal with the albumen of the tissues!

UREA AS AN ANTIPERIODIC.—Urea, which is used by homœopaths for diabetes is now recommended (*Weekly Med. Review*) by Dr. Belvouseff as an efficient substitute for quinine. He asserts (*Journal d'Hygiène*) that carbanide has a specific action in intermittent fever; that it can be employed in many other complaints as an antipyretic; that it is an efficient germicide, killing bacteria and vibrios instantly. It is tasteless, and does not depress the nervous system, and is much cheaper than quinine. In Southern Russia and Montenegro the use of urine as a cure for intermittent fever is common among the peasants. Several years ago the attention of the profession was called to the value of a double salt of urea and quinine for use by hypodermic injection instead of the other salts of quinine, the claim for it being that it was less irritant, and equally, if not more efficient. The facts just cited, as to the therapeutic qualities of the urea, will explain and guarantee these claims.

Progress of Medical Science.

FEVER A NEUROSIS.—Dr. W. Finkler (*Pflüger's Archiv*, vol. xxix.) has made an elaborate study of the phenomena of fever experimentally produced in animals. Since Tcheschicin first announced that there was a centre inhibiting the production of heat, there have been no very exact methods carried on to prove the fact. Finkler, however, has selected a very accurate method to settle the question; that is, a quantitative estimate of the oxygen absorbed and of the carbonic acid given off. In Pflüger's school at Bonn, it has been found that in guinea-pigs cold increases in a very regular manner the generation of carbonic acid and the consumption of oxygen. In this school it has also been shown that in poisoning with curare the production of carbonic acid and the absorption of oxygen fall greatly, showing that the nervous system is a factor in the tissue metamorphoses. It was also further established that section of the medulla oblongata was followed by similar results, there being here a partial elimination of nervous action. Finkler measured the oxygen consumed and the carbonic acid given off, and compared these with a time unit and the weight of the animal. From his experiments the law is deduced that the consumption of oxygen is greater during the fever-elevation of temperature than during the non-febrile state, under like conditions of food and surrounding temperature. He also thinks that in fever an increased amount of carbonic acid is given off, due to increased heat-production. When the oxidation passes through the three phases of increase, continuance at a height, and decrease, it corresponds only in a general way to elevation, continuance at a height, and decrease of temperature. Finally the author concludes that fever is mainly an affection of that portion of the nervous system which regulates temperature.

INSANITY IN THE UNITED STATES.—The ratio of insanity to the population is lower in the United States than in any other civilized country, and would be still lower if estimates could be limited to American born inhabitants. At least so says Dr. Everts, of the Cincinnati Sanitarium, in his annual report. One fact which swells the number of insane reported is that "almost all adults of the feeble-minded class are enumerated as insane." This is no less true in other States than in Illinois, where it was noted specially by Dr. Wilbur, of the Asylum for Feeble-Minded Children of that State. Dr. Everts expresses a truth which we all recognize when formulated, in saying: "With us it is more reputable to be mad than to be weak, and our public provision for those who have lost their reason is much more pretentious, if not more generous, than for those who never had much, if any, to lose." He thinks there is no ground for believing that insanity as a disease is increasing in this country. The causes of insanity are such that in the opinion of Dr. Everts, the American people may be assumed to have a comparative exemption from the disease. Life insurance records and the army statistics show that the organic heritage of the American people is superior to that of European natives, while it is unquestionable that ours is the best fed people in the world. Again, the disease drunkenness is less common among Americans of the present day than among their immediate or remote ancestors, and less common, too, than among the present inhabitants of Northern Europe, to whom they are so intimately related.—*Weekly Medical Review.*

NEW METHODS OF REDUCTION OF DISLOCATIONS OF THE THIGH.—In cases where reduction of the femur by manipulation in the usual way, with the aid of anæsthetics, has failed, or is inapplicable, and as a substitute, in many cases, for anæsthesia, assistants, and mechanical power, Dr. Kelly proposes the following methods:

For posterior dislocations.—The patient is laid prostrate upon the floor. Three strong screw-hooks are in-

serted into the flooring close to the perineum and each ilium of the patient, and to these hooks he is secured by strong bandages or rope. The injured thigh is flexed at right angles to the patient's body; the foot and lower extremity of the tibia are placed against the perineum of the surgeon, who, bending forward, with the knees slightly flexed, passes his forearms behind the patient's knee and grasps his own elbows. Reduction is now accomplished by drawing the femur upward. But circumduction may also be practised; the surgeon stepping backward, then extends the limb, and lays it by the side of its fellow. In sciatic dislocations in order to liberate the head of the bone from the foramen a bandage may be passed around the thigh, close to the trochanter, by which an assistant may make traction.

For anterior dislocations.—The patient is placed upon a table of such elevation as to have his pelvis nearly as high as the trochanter of the surgeon. A bandage around the pelvis, and secured to the side of the table farthest from the dislocation affords counter-extension. The surgeon, with his face directed toward the dislocated joint, and standing on its inner side, with his trochanter pressed against the femur, now bends the leg behind his back, and grasps the ankle with the corresponding hand. Reduction is effected by rotating or turning his body partially away from the patient, thus making traction on the femur in the most favorable direction, and at the same time pressing his head toward the acetabulum with the disengaged hand.—*The Practitioner*, March, 1883.

IS CRANIOTOMY JUSTIFIABLE.—From an analytical study of the subject, Dr. Montgomery (*Philadelphia Medical Times*, March 10, 1883) is inclined to answer the above question in the negative. He terminates his studies by stating the following proposition: Craniotomy is unjustifiable, as, 1st, it considers only the life of the mother, and destroys that of the child, while it is our duty to endeavor to save both. 2d. In pelvis with a conjugate diameter greater than $2\frac{1}{2}$ inches we have other alternatives equally safe for the mother, which afford the child a chance for life. These alternatives we would suggest in the following order: Where the conjugate measures 3.25 inches or over, the forceps; 2.75 inches or over, version; $2\frac{3}{4}$ inches or over, symphyseotomy, followed if necessary by the forceps. In all subsequent pregnancies, and in the first when distortion is discovered sufficiently early, premature labor should be induced. 3d. In pelvis measuring less than $2\frac{1}{2}$ inches, Cæsarean section affords better results for the mother, and should be done whether the child be living or dead.

In a limited number of cases (where the os is dilated) laparo-elytrotomy may be preferred to Cæsarean section. In all cases requiring it, operative interference should be early. The obstetrician should control events, not be controlled by them.

PICRIC ACID AS A TEST FOR ALBUMEN IN THE URINE.—For the detection of albumen, Dr. Johnson (*British Medical Journal*) recommends that this acid should be used in the form of a saturated aqueous solution, or in the form of powder or crystals. The aqueous solution is most suitable for home use, while the powder or crystals may conveniently be carried in a urinary pocket test-case. A saturated aqueous solution may be quickly made by adding about fifty times the bulk of boiling distilled or rain water to the powder or crystals, a portion of the acid will crystallize out on cooling, leaving a transparent yellow supernatant liquid. This solution being added to an equal volume of albuminous urine in a test-tube, immediately coagulates the albumen. The coagulated picrate of albumen is soluble in alkalies; if, therefore, the urine be highly alkaline, it must be acidulated by a vegetable or a mineral acid before adding the picric acid solution. In numerous testings for albumen with picric acid, the author has not once found it necessary to acidulate the urine. The picric acid solution is itself sufficiently acid to dissolve the phosphatic sediment which

results from boiling a neutral or alkaline specimen of urine. To detect a very minute quantity of albumen, the following method is the best. Into a test-tube about six inches long the urine is poured to within two inches of the top: then, the tube being held in a slanting position, about an inch of the picric acid solution is gently poured on the surface of the urine, where, in consequence of its low specific gravity (1.003), it only partly mixes with the upper layer of the urine; and, as far as the yellow color of the picric solution extends there will be more or less turbidity from coagulated albumen, contrasting with the pellucid unstained urine below. If, then, the tube be placed in a stand, the coagulated albumen will gradually subside, and form a delicate horizontal film at the junction of the colored and the unstained stratum of urine, the yellow liquid above and the uncolored urine below being quite free from turbidity. If the urine should be turbid with urates, it must be cleared by heat before the addition of the picric acid solution.

As a result of numerous observations, Dr. Johnson has arrived at the conclusion that picric acid applied in this way is a more delicate, and therefore more trustworthy, test for albumen than nitric acid in cold urine, whether the latter be employed by the method of dropping the acid into the cold urine or by pouring the urine on the acid previously placed in the tube. The simplest and most satisfactory mode of comparing the two tests as regards their relative delicacy, is to dilute a specimen of albuminous urine until one or the other test fails to act; and it will be found that the picric acid solution shows the presence of albumen in a specimen diluted considerably beyond the point at which the nitric acid fails to give any indication. The picric acid, too, often causes an immediate albuminous opalescence in specimens in which nitric acid only slowly, and after an interval of some minutes, gives a similar, but sometimes a doubtful, indication.

ERGOTINE INJECTIONS FOR HYDROCELE.—Dr. Walker, says (*British Medical Journal*) that, owing to an accidental substitution, he injected two drachms of liquor ergotæ, instead of the same quantity of tincture of iodine into the sac of a hydrocele. The result was very gratifying, there being a radical cure without the slightest reaction. He has since repeated this method with perfect success, and prefers it to other plans of treatment.

PRIAPISM IN LEUCÆMIA.—Dr. Carl Kétli, at a recent meeting of the Medical Society of Budapest, Hungary, exhibited a patient who had been suffering from painful priapism for two weeks and had not been benefited by the use of bromide of potassium, lupuline, and various other measures undertaken for his relief. Spinal disease was not present, but the patient showed all the characteristic symptoms of splenic or medullary leucæmia. Similar cases have been described heretofore by Longuet (*Progrès Medical*, 1875, No. 32), and Salzer (*Berliner Klinische Wochenschrift*, 1879, No. 11).—*Orcosi Hetilap*, March 4, 1883.

SASSAFRAS IN RHUS POISONING.—Dr. R. L. Hinton claims that sassafras tea is almost a specific for the rash produced by poison oak. This is an infusion of the bark of the red sassafras. The diseased parts are covered with compresses soaked in the cold infusion, while internally there is administered the infusion warmed, sugared, and with milk, according to the taste.

PRIMARY TUBERCULOSIS OF THE INTESTINES.—The existence of tuberculosis of the intestines as a primary affection has been denied by several writers. Dr. Koczynski, however, affirms its occurrence and cites a case in proof. A previously healthy man, forty-seven years of age, began to suffer from pain in the abdomen after having lifted a heavy beer-keg. He lost appetite and strength, and general anasarca supervened. The stools were frequent, thin, and slimy. After a time he began to complain of constant pain to the right of the umbili-

cus, and upon palpation a tumor the size of an apple, soft, elastic, and very tender, could be felt. This tumor disappeared from time to time and reappeared with borborygmus and inclination to stool. The diagnosis was made of tuberculosis of the small intestine with consequent circumscribed peritonitis and constriction of the gut. At this time there were no signs of disease in the lungs. Later, the lungs gave evidence of being affected. After death the autopsy confirmed the diagnosis. There was a tuberculous tumor in the ilium with secondary peritonitis. There was a recent disseminated tubercular infiltration in the lungs without any cheesy collections. The author thinks that the injury received in lifting the heavy weight caused a slight inflammation of the ileum, which inflammation determined the localization of the previously latent tuberculosis.—*Centralblatt für Klin. Med.*, February 3, 1883.

DIABETIC AND NEPHRITIC NEURALGIAS.—Dr. Berger has analyzed a number of cases of neuralgia depending upon diabetes or nephritis. He states that these neuralgias affect usually the sciatic nerve, and more particularly single branches of this nerve, such as the plantar or aural. They show a tendency to affect both sides symmetrically, are often associated with vaso-motor symptoms, and are exceedingly obstinate to treatment other than that directed against the primary disease. The severity of the neuralgia bears a direct ratio usually to that of the causal disease, although in the cases under consideration it was by means of the former that the organic trouble was discovered. The author is inclined to regard these neuralgias as having a central origin.—*Centralblatt für Klin. Med.*, February 10, 1883.

PHOSPHORUS IN THE TREATMENT OF OSTEOMALACIA.—Dr. W. Busch reports two cases of osteomalacia treated by phosphorus. The first patient was a fairly healthy-looking woman, thirty years of age, in whom the disease appeared a few weeks after childbirth. The objective signs were confined to the bones of the pelvis. This presented the appearance of having been pressed together from the sides. The symphysis projected forward like a beak, while the horizontal rami of the pubes were sharply bent. Walking was impossible, the patient being able only with the greatest difficulty to move from the bed to a chair. Absolute rest in the horizontal position was ordered to be maintained for three months, and Wegner's phosphorus pills were prescribed. After five months' treatment the patient was able to go up and down stairs without difficulty. At this time she changed her residence and passed from under observation. The second case was that of a woman, fifty years of age, who complained of intense pain in the right arm near the insertion of the deltoid muscle. A diagnosis of osteitis was made and the ordinary measures were prescribed. No improvement was noticed, and after several weeks the patient abandoned the treatment. In about nine months she again came under observation. She was then reduced almost to a skeleton, was absolutely unable to walk, and was greatly deformed. The dorsal spine was kyphosed, while the cervical spine was so strongly lordosed that the head seemed to rest between the shoulders. The thorax was distorted, the femora were bowed, and the pelvis presented the characteristic deformity of osteomalacia. The patient was confined to the bed for seven months, and took Wegner's pills for a year and a half. At the end of this time the bones were firm, and she could go about without complaint. The deformity was not decreased. The following is the formula for Wegner's pills: ℞. Phosphori, 0.025; syr. simpl., 7.5; M. bene et adde pulv. glycyrrh. rad., 10.0; pulv. gummi arab., 5.0; gummi tragacanth., 2.5; ft. pil. No. 250. Each pill contains about $\frac{1}{850}$ grain of phosphorus. The dose is one pill twice a day, to be gradually increased. Busch does not consider the drug to be of any value in rickets or caries.—*Centralblatt für Klin. Med.*, February 10, 1883.

PERITONITIS NEONATORUM.—Dr. Oscar Silberman recognizes two varieties of peritonitis in the new-born. The non-septic or chronic form is developed usually in the first third of fetal life, and is generally syphilitic in origin. If the peritoneum covering the intestines be involved, as well as that over the liver and spleen, various forms of intestinal obstruction may result. Most frequently we find occlusion of the anus, less often stenosis or complete occlusion of the small intestine. Of a number of cases of congenital occlusion of the intestine, collected by the author, all ended fatally, only one living beyond twelve days. The second, acute or septic, form of peritonitis in the new-born the author divides into two varieties, according as the peritonitis is only a part of the general infection or is the sole manifestation of the septic poison. In either case the point of entrance of the poison is always at the navel wound. The symptoms, which need not all be present in a given case, are vomiting, watery stools, meteorism, ascites, abdominal tenderness, icterus, etc. The pulse, temperature and respiration may vary in degree in the different cases. A cure of the septic form is possible; therefore, the treatment should be carefully considered. The navel wound must be cleansed, and the child is to be isolated from its mother. To control the fever quinine may be given. The Priessnitz sheet is of value. Vomiting may be checked by chloral (one-half to one grain in water). The strength should, of course, be maintained by stimulants if necessary.—*Schmidt's Jahrbücher*, January 17, 1883.

FOOD MAKES THE MAN.—Speaking roughly, says the *London Lancet*, about three-fourths, by weight, of the body of man is constituted by the fluid he consumes, and the remaining fourth by the solid material he appropriates. It is therefore no figure of speech to say that food makes the man. We might even put the case in a stronger light and affirm that man *is* his food. It is strictly and literally true, that "a man who drinks beer thinks beer." We make this concession to the teetotalers, and will add that good sound beer is by no means a bad thought factor, whatever may be the intellectual value of the commodity commonly sold and consumed under that name! It cannot obviously be a matter of indifference what a man eats and drinks. He is, in fact, choosing his animal and moral character when he selects his food. It is impossible for him to change his inherited nature, simply because modifications of development occupy more than an individual life, but he can help to make the particular stock to which he belongs more or less beery, or fleshly, or watery, and so on, by the way he feeds. We know the effect the feeding of animals has on their temper and very natures; how the dog fed on raw meat and chained up so that he cannot work off the superfluous nitrogenized material by exercise, becomes a savage beast, while the same creature fed on bread and milk would be tame as a lamb. The same law of results is applicable to man, and every living organism is propagated "in its kind" with a physical and mental likeness. This is the underlying principle of development. Happily the truth is beginning, though slowly and imperfectly, to find a recognition it has long been denied. It is possible that in the natural desire to secure the best and purest supplies of food and drink for man we are pushing matters a little to extremes and becoming ridiculous. Utopia is a long way off, and "Hygeia" has not yet been built. It is, however, desirable that we should aim high and make the teachings of physiological science the precepts of our daily life and conduct. We may not be able to reach our ideal, but progress will be advanced by striving to make its attainment an object. "What to eat, drink, and avoid" is a rational proposition; and if some of us are becoming a little unreasonable in the attempt to solve it, at least we are on the right road, and ought to be encouraged rather than abashed by the, not unkindly, criticism our endeavors are calling forth.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 14, 1883.

SEWER GAS, AND ITS ALLEGED CAUSATION OF TYPHOID FEVER.

In a paper recently presented before the College of Physicians of Philadelphia, by Dr. George Hamilton, some very excellent arguments are brought forward relating to the causation of typhoid fever, as opposed to the opinion that sewer gas is the principal agent in the production of this disease, and more than equal, singly, to all other causes combined. While admitting the importance of the vehicle sewer gas as one element in this direction, numerous instances are cited, supported by facts founded upon personal observation and inquiry, and upon statistics, in which sewer gas played no part whatever, and showing that the larger number of cases of typhoid fever occur altogether independently of this influence. Indeed, the weekly reports of the health boards of Philadelphia and New York City, and, in contradistinction, the practical experience and investigation of eminent authorities, show that typhoid fever has always been far more prevalent in the suburbs and surrounding country than in the cities subjected to the contamination of sewer gas.

That sewer gas is, however, a prominent factor in the causation is not denied; but upon this foundation enthusiasts have built until the credulity of public opinion has accepted the mountain, while other agents, the little mole-hills, which possess not only an equally important, but even a greater, influence in this respect, are almost totally ignored.

Regarding the declaration that there is in country houses, or the surroundings, something equivalent to sewer gas, personal experience has shown that the young men at work in the fields were more frequently attacked than the females, who were generally engaged in domestic duties in or about the house. The same results are also exhibited of diphtheria and scarlatina, as to the causation of these maladies by this agent, the most fatal attacks occurring in the country where sewer gas is wanting. Furthermore, experience justifies the assertion that in not more than one house out of five has any evidence of sewer gas been detected, either before or during an attack of typhoid fever. If, also, the opinions of some eminent authorities are correct that the plumbing apparatus, as at present constructed, is incapable of excluding the gas, and that the dwellings of New York City and Philadelphia are so thoroughly infected, the self-evident conclusion is that the mortality would be something frightful. Again, instances are recorded where individ-

als returning from the country to their city homes have been taken with typhoid fever in a very few days, and before the incubative period could have passed. And others where the disease has appeared among the wealthier residents of the country, where the surroundings, the farm, the agriculture, domestic and general economy have been exceptionally good. Yet all this has often occurred without the influence of sewer gas or, to all appearances, of any of the other agents which are usually held responsible. And the experience of extensive practitioners, both in town and country, almost invariably serves to show that typhoid fever, when it appears in the country, is far more general and more fatal than in the city, and that it is, as a rule, impossible to trace its origin.

Attention is also directed to the habit, by professed sanitarians, of expatiating on the unnecessary prevalence of the so-called "filth diseases"—typhoid fever, scarlet fever, and diphtheria—in large cities, while, at the same time, they seem unmindful of the great excess in the ravages of these same diseases in the country, both in proportionate number of cases, in violence, and in fatality. In connection with this it is further shown that in the central portions of Philadelphia, where sewers and water-closets most abound, there is, as a rule, less typhoid than in the adjacent country; and just in proportion as the city encroaches upon the rural sections, constructing streets, houses, and sewers, a diminution in the fever has invariably followed. The condition of the streets of one or two of the most populous cities of Africa are also mentioned, where every species of filth abounds, and yet typhoid fever prevails only to a very slight extent.

In regard to the contamination of drinking water acting as a cause, while this is unquestioned, yet it is reminded that the quality of the water remains essentially the same from year to year, whether typhoid prevails extensively or is absent. In this connection, however, should not individual susceptibility also receive consideration? And, moreover, is not the fact of the streets of Africa, etc., reeking with filth and stench, while the statistics of that region show a comparative immunity from the disease, but a blow at every generally accepted cause of typhoid fever, since nothing would seem to be wanting among such surroundings but the appearance of even one single case?

Admitting the various factors, then, can the preponderant one be selected by exclusion. Possibly water-pollution may claim the foremost rank, but is this simply because the use of water is universal and its infection so easy a matter? May it not be fair to assume that, at least in the primary exhibition of the disease, the peculiar state of the constitution holds an important part. The acarus scabiei cannot thrive in every soil. May not also the typhoid germs (presupposing their existence) often fail to set up their specific condition, particularly when taken into a healthy and robust constitution; and may not the drinking water be essentially the same from year to year—be infected—and yet the germ fail to excite its disease, until the particular individual or the special state offers? While, therefore, the numerous elements brought forward in this direction are important in their several bearings, yet it must finally be admitted that the intimate and primary cause of typhoid fever is, at present, one of the most obscure problems of medical science.

THE WHOLESALE PREPARATION OF DRUGS AND MIXTURES.

New Remedies publishes the following letter, from a correspondent, concerning what is termed "a growing evil."

"The leading pharmacists of this city have had several meetings recently to consult in regard to the prescribing by physicians of special preparations emanating from the large manufacturing establishments. This practice is working to the injury of both the physician and pharmacist. The pharmacist, in order to hold his trade, is obliged to keep in stock a full line of similar preparations from perhaps half a dozen different makers, and the physician often loses his fees, from the patient finding out that he can purchase the remedy prescribed in original packages, and at reduced rates, from the fancy goods dealer or the wholesale druggist, and will continue the use of the medicine, and if benefited, recommend it to a friend, without giving his doctor the credit by sending him other patients. It is now proposed, and an able committee has been appointed, to get up a uniform set of formulas for the preparation of the different elixirs, syrups, and other products of elegant pharmacy, so called, for the use of the pharmacists and physicians of New York and Brooklyn, so that after the adoption and publication of these formulæ the physician may send his patient to any respectable pharmacy, confident that his prescription will be filled with a uniform and reliable preparation, which cannot be obtained by the patient in any other way than by his order."

The preparation of a set of formulæ such as is suggested will no doubt be useful. The whole matter, however, appears to be one of greater interest to the pharmacist and the public, than to the physician. The manufacture and extensive advertisement of special mixtures containing numerous vegetable drugs in unknown proportions "so combined as to produce peculiarly valuable effects" has become very popular of late. This practice tends to demoralize legitimate therapeutics and is not to be commended. The manufacture, however, of officinal drugs, singly or in various combinations, and the putting them upon the market in attractive form, has much to be said for it, and we do not share the fears of the correspondent quoted above, that such action of itself injures the physician's practice or diminishes his income.

THE CLINICAL TEACHING OF MENTAL DISEASES IN AMERICAN COLLEGES.

The National Association for the Protection of the Insane and the Prevention of Insanity has issued a circular addressed to the various medical colleges of the country, and asking that the didactic and clinical teaching of insanity be introduced. The circular is signed by Dr. E. C. Seguin, Dr. M. Putnam-Jacobi, and Dr. Margaret Cleaves.

With the increased prominence now being given to clinical teaching, it is most proper that mental diseases should receive their share of attention also. Every medical student ought certainly to see some of the various types of insanity before graduating, and be able to recognize their salient features. We have often insisted upon the need of a better knowledge of insanity on the part of medical men, believing that such a knowledge would be

a powerful factor in preventing and lessening the disease. The recommendations of the National Association will appeal to every one as wise and sensible.

We understand that there are already nearly a dozen colleges which have lectureships on mental disease, but that very few of these attempt any clinical instruction. It is this latter alone which will give value to the teaching.

THE NOURISHMENT OF CHILDREN AFFLICTED WITH HEREDITARY SYPHILIS.

THE question of the nourishment of children afflicted with hereditary syphilis is one upon which there is considerable diversity of opinion. Most authors agree that the lives of this unfortunate class of beings can only be preserved by a strict diet of human milk. But writers are less unanimous in their views as to the best means of obtaining this nourishment. Zeissl advises (*Centralblatt für Gynäk.*, February 3, 1883), in case the child of a syphilitic mother shows no signs of hereditary syphilis, that a nurse be procured. He argues that, even if the milk cannot convey the poison, it is yet unhealthy and unfit for the nourishment of the child. In the other case of a syphilitic child born of a healthy mother, Zeissl thinks it safe, as a rule, to let the mother suckle her infant. Yet Colles' law*, that a child cannot infect its mother in nursing, is not without exceptions. Two of these have already been recorded, and the author cites a third case related to him by Dr. Lüth. If a nurse be employed she should be warned of the possibility of infection. Eisen-schitz (*Centralblatt für Klin. Med.*, February 3, 1883) agrees with Fournier and Fürth that the infection of the nurse is certain to occur, and, therefore, insists that the mother herself should suckle the child. A nurse should be procured only when the mother is absolutely unable to nourish the infant, and when the prognosis for the latter is favorable. And she should, of course, be warned of the danger to which she is exposed.*

THE ACTION OF CALABAR BEAN UPON THE INTESTINE.

A NUMBER of authorities have commended the use of calabar bean on account of its peculiar power of stimulating intestinal peristalsis. Subbotin and Schaefer, of Bonn, have especially called attention to its value, but we find mention and commendation of it in nearly all the modern therapeutical works. At the Berlin Veterinary School, and at the Columbia Veterinary College and School of Comparative Medicine in New York, eserine, the active principle of physostigma, has been used with remarkable results in the obstinate constipation and colic of horses. Grain doses of the drug injected into the jugular vein, or subcutaneously, will, it is said, cause movements when everything else has failed. Subbotin has reported a similar experience in cases of obstinate constipation in man.

The attention that has been called to the value of calabar bean as a tonic and stimulant to the intestinal musculature gives a special interest to a recent communication by Dr. A. Hiller, of Berlin, detailing his experience. He employed a fluid extract of calabar bean, one part in three hundred of glycerine, and gave ten drops three or four times daily. He confirms the statements of Subbotin that calabar bean is a rapidly acting remedy

in atonic conditions of the intestinal tract, and is useful in the flatulence and oppression which accompany this atony. He adds, however, that in his experience the drug has a temporary action; that after a few days the intestine seems to become less responsive, and that then the fluid extract must be given in doses which are likely to produce toxic symptoms. Furthermore, Dr. Hiller states that he has never known the physostigma alone, in safe doses, to produce an evacuation. It must be given with aloes, castor oil, or some other purgative. The writer concludes that if one wishes to use physostigma as a tonic to the intestinal wall, he can safely give the drug for only two or, at most, three days, using doses of 1.5 to 3 milligrammes three or four times daily. An early evidence of toxic action is found in the narrowing of the pupil.

Calabar bean, when given in large doses to rabbits, was found by Hiller, as has been done by others, to produce at first increased peristalsis, but finally a tetanus of the intestinal wall accompanied by great anæmia. Hiller suggests that possibly the drug, in large doses, may be useful in cholera, since it produces the opposite condition to that of the disease in question. Some years ago this idea was broached by Mapother and by Munro. The drug was, we believe, tried, but the results were not very satisfactory.

AIR-BATHS.

DR. FRANKLIN is credited by the *Boston Journal of Chemistry*, March, 1883, with the discovery of a sanitary or curative agent called the air-bath. It is certainly a matter of common experience that the application of cold or warm water is not equally well borne by all. Indeed, some invalids, convalescents, or enfeebled persons have experienced deleterious effects from bathing as ordinarily used. In certain conditions of the body, sponging, douching, the wet-sheet, and especially the popular Turkish and Roman baths, or similar ordeals, may be readily conceived to be measures of doubtful hygienic value. Yet attention to efficient cutaneous action is never out of place. Now, it is for the benefit of persons who do not bear well any kind of "water-cure," that it is proposed to substitute the air-bath as a means of, or, at least, an aid to recuperation.

We are told by the author that the morning is the best time for the air-bath, and all that is required is a hair-cloth mitten and a moderately cool room. Here are the directions for this new kind of bathing: Let the invalid step from the bed to the floor, seize the hair glove or mitten, and without removing the night-clothes proceed to rub gently all parts of the body, at the same time walking about in the room until a feeling of fatigue is experienced. Then drop the glove, and gently pass the hand over all parts of the body before resuming the clothing. Unless the nude body is extremely sensitive to cold, a portion may be exposed to the air for a few moments while in motion, even on the first morning. The next morning jump out of bed in a moderately cool room, and go over the same process as before, remaining a little longer exposed to the air after the rubbing. The third morning repeat this treatment; and on the fourth, or at the end of a week, take off all the night-clothing, and briskly apply the hair glove, first with the

right hand and then with the left, all the time walking about. Follow up this as the degree of strength permits, morning after morning, until the blood is so attracted to the surface, that the cool air is felt to be a luxury. Let the body be entirely nude. At first, or after the first week, perhaps, the exposure to the pure cool air may be three or four minutes. Soon this may be increased, until, after a month or two, the air-bath may continue for twenty minutes or half an hour. It is essential to walk about during the first month, using the hands in polishing the skin. Later on the patient may sit in the air of the room part of the time. But constant, gentle exercise is best.

Now, according to the author, another most important curative agent connected with the air-bath is sunlight. In summer, this is easily accessible, but in winter only the late risers can secure its benefits. Exposure to sunlight during the air-bath apparently enhances its hygienic value. It is thought that the direct actinic rays of the sun may have some very beneficial properties. We are not aware that air-bathing has already become universally recognized as an important aid in re-establishing normal vitality in enfeebled constitutions. Judged *à priori* the method appears to commend itself in certain selected instances. Yet it will scarcely supplant the popular aqueous ablutions, as a healthful, delightful, and time-honored practice.

CURE OF SQUINT WITHOUT OPERATION.

IN the early stages of convergent strabismus, before the internal rectus muscle is permanently contracted, Dr. Boucheron (*Schmidt's Jahrbücher*, January 17, 1883) claims that a cure is possible without operation. He states that as convergence is caused by efforts of accommodation for near objects, if we take away the power of accommodation squint will not occur. He maintains a constant mydriasis by the instillation of atropine night and morning. A cure is usually obtained in two or three weeks. If atropine is not well borne, other mydriatics, such as duboisia, may be used. In nine cases of intermittent strabismus the author obtained eight cures by this method.

THE METHOD OF BRANDT.

DURING the late epidemic of typhoid fever in Paris, upward of six thousand persons were attacked with the disease, and the mortality was nearly thirty-seven per cent. In three months the number of deaths was 1,358. These facts may be some excuse for the interminable discussion regarding typhoid fever which has been going on in the Académie de Médecine since last Fall.

One of the features of this discussion was the appearance of a Lyons physician, Dr. Frantz Glenard, who came up to Paris as a representative of the Faculty of his city, and as an apostle of the method of Brandt in the treatment of typhoid fever. Glenard has long been known as an enthusiastic advocate of hydrotherapy in this disease. His first and second monographs on the subject have been quite widely circulated. A third monograph, published two years ago, contrasted the use of cold baths with that of phenic acid, very favorably to the former.

In Glenard's later writings he states that, while the mortality from typhoid fever without cold baths was 22 per cent. in 33,293 patients, with cold baths, as directed by Brandt, the mortality has fallen to 7.4 per cent. in 8,141 cases. The report of M. Strube, Medical Director to the Prussian Minister of War, is quoted, in which it is stated that in several army corps where the Brandt method was tried, the mortality fell from thirty to three or four per cent. Glenard claims that the hospital physicians of Lyons, almost without exception, have adopted the method of Brandt.

There is a certain lack of definiteness and authority about Dr. Glenard's statistics, and we cannot find that he now brings forward very much new evidence for his hobby. He firmly believes, however, that the method of Brandt strictly carried out will reduce the mortality from typhoid fever to three per cent. We hope he is right, but in America, at least, there have been no clinical results which in the least support this pleasing view.

THE STATE MEDICAL SOCIETY AND A TURN IN THE TIDE.

It is gratifying to observe the change which is taking place in the attitude of the American medical press and profession toward the New York State Medical Society. One year ago THE MEDICAL RECORD and the *New York Medical Journal* were almost alone in defending the position assumed by this Society.

Now matters are much changed. The *Buffalo Medical and Surgical Journal* accepts the action taken last February; the *Medical Annals* ably defends it. The *Medical Age*, one of the best edited and most representative journals in the West, sides with those who believe that the position of the profession will be elevated by not attempting to antagonize homœopathy, or to enforce a petty and ineffective discipline. The *Weekly Medical Review*, perhaps the most wide-awake and progressive of medical journals west of the Alleghanies, takes an impartial position, and admits arguments on both sides. The *Indiana Medical Monthly* shows in a recent editorial how foolish, exaggerated, and unjust have been the criticisms against New York's action. It is quite willing to wait and learn from this State's experience. The *Southern Clinical Review* and, we believe, the *Northwestern Lancet* side with the position taken by our State Society. The *Virginia Medical Monthly* comments with great fairness upon this position; so also does the *Maryland Medical Journal* and the *New Orleans Medical and Surgical Journal*. The *Independent Practitioner* is non-committal.

To all this we should add the weighty effect of the doctorate address delivered by Professor Moses Gunn and published in the *Chicago Medical Journal and Examiner*, as also that of the Presidential address by Dr. Alexander Stone, Vice-President of the American Medical Association.

It is no longer possible, therefore, to say that the medical profession universally disapproves of allowing freedom in consultations.

Under the influence of maturer thought, kindly and sensible feelings have developed. The efficacy of fanatical and abusive declamation has spent its force. The question is reaching the right basis for fair discussion.

THOMSEN'S DISEASE.

PROFESSOR WESTPHAL recently showed to the Berlin Medical Society two patients suffering from a very unique affection which he christened at the time, and very appropriately, with the name of "Thomsen's Disease." Dr. Thomsen, a general practitioner in Schleswig, first described the trouble in 1876, having himself been a victim to it all his life. Since his description was published only eight similar cases have been reported, and so far the disease appears not to have been observed in France, England, or America.

The prominent symptom is the following: When the patient under certain circumstances attempts voluntary movements, the muscles undergo tonic contraction, and the movement is stopped or hindered. Thus, after long sitting or standing, if the person tries to move, he finds his muscles so stiff that it is at first impossible to stir. The same thing follows after rapid and powerful muscular movements. The unfortunate patient, in trying to run or dance, is suddenly overcome with muscular stiffness. If he throws a stone, the extended arm remains rigid. Sudden irritations, either physical or mental, also bring on the spasm. If, while walking along, the foot strikes a stone, the leg becomes rigid and the patient may fall down. In some of the cases simply concentrating the mind upon the trouble would bring on some evidences of it.

The spinal nerves are most affected, but the innervation of the face, and even of the ocular muscles, is partially interfered with. The smooth muscles are not disturbed. The muscles undergo an increase in volume, though not in proportionate strength. Their electrical reactions are unaffected. Microscopic examination of the fibres shows nothing abnormal. The reflexes are normal. Sensibility is undisturbed and the contractions and stiffness do not cause pain.

The cause of the disease is not known, but it has a curious hereditary tendency. In fact most of the cases have occurred in Dr. Thomsen's family, where it has been traced through four generations. Dr. Thomsen was inclined to think that the trouble had a psychical basis, but Westphal believes it to be an anomaly of the muscular tonus. Treatment accomplishes little or nothing. The disease is a pathological curiosity and a highly interesting one.

THE PROPOSED JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

WE had occasion recently to refer to the statements of the committee on the proposed journal of the American Medical Association, and suggested that the estimates of the yearly cost of the scheme, and a definite statement of the encouragement received be published at once. We have neither heard nor seen anything in response to this practical and common-sense advice.

Surely the members, who are individually to become liable for any deficit in the annual accounts, and in our judgment a deficit is more than probable, should have the fullest opportunity to consider the prospective debit and credit sides of this account.

If the committee have the figures, as they say they have, let the items be published now; if they are favor-

able to the plan, it can do no harm; if they do not satisfy all, the Association will, at least, have the satisfaction—if it concludes to start the journal—of knowing that it went into it with its eyes open. To withhold the figures, upon which alone an intelligent judgment can be made, until the time of the meeting is quite unfair and unjust to the members generally. Shall we have light?

News of the Week.

THE NORTH CAROLINA BOARD OF HEALTH has failed to receive an appropriation from the Legislature.

THE NEW YORK POST-GRADUATE SCHOOL AND THE NEW YORK POLICLINIC.—We are glad to learn that both the above institutions have prospered beyond expectation during the past season. The present courses are larger than ever. They will continue open during the spring and summer, a fact which will be much appreciated by many physicians who cannot easily come to New York in the winter season. The advantages which these post-graduate schools possess is the ability to offer direct and personal instruction in technique and in symptomatology.

SIR WILLIAM JENNER has been re-elected President of the Royal College of Physicians, London.

DEATH OF PROFESSOR VON BRUNS.—The death is reported of Professor von Bruns, one of the highest surgical authorities in Germany. The deceased, who was born in 1812, in Brunswick, was the author of several surgical treatises and handbooks, and made a special study of diseases of the larynx, for the treatment of which he invented a new and effective throat-mirror. His work on laryngoscopic surgery gained for him the grand prize of 20,000 marks offered by the Academy of Turin.

THE KENTUCKY STATE MEDICAL SOCIETY held its twenty-eighth annual session on April 4th, at Louisville. A large number of members were present. The address of welcome was delivered by Dr. Coleman Rogers, who referred to the fact that, in accordance with a previous resolution, no special entertainments would be offered the Society, which was expected to devote itself to scientific work alone.

A letter was read from Dr. S. D. Gross, in which he said: "Forty-two years have elapsed since my then colleague, the lamented Drake, and I were deputed by the Medical Faculty of the University of Louisville as delegates to attend a convention at Frankfort, called at the instance of Dr. George Sutton, of Georgetown, to assist in the formation of a State medical society, of which the present Society is the offspring. The attempt was a signal failure, and it was not until the following year, if indeed so soon, that Dr. Sutton's efforts were crowned with success.

"Since the date of my visit vast changes have taken place in and outside the profession. Medical education has been greatly improved, and the practice of medicine has assumed many new features, while many of its branches have been completely revolutionized. All my old colleagues, with the exception of two, of the University of Louisville, are dead, and most of my old personal

friends of Louisville are mouldering in their graves. My own days are numbered; time has made me an old man, and I cannot expect to attend many more public meetings of any kind. All that I can do is to send you and all the rest my love and my best wishes for your and their prosperity and happiness. Always truly your friend."

The annual address was delivered by Dr. A. D. Price, and was sensible and practical in character. He touched upon the subjects of medical education, trained nurses, legalizing prostitution, and specialism in medicine.

ACTION OF THE ILLINOIS STATE BOARD OF HEALTH IN RELATION TO THE COLUMBUS MEDICAL COLLEGE.—The following action of the Illinois State Board of Health was had at its meeting, January 12, 1883:

"*Ordered*, after a careful investigation of all the essential facts in the case of the Columbus Medical College, two members of the Faculty of said College being present, and the facts elicited being confirmed by documentary evidence, that, while said College committed an irregularity in granting a diploma to A. M. Dent, that irregularity does not seem to warrant this Board in refusing to recognize other diplomas of said College."

We are asked to add, in regard to the "Dent" case that the Faculty "presented to said Board evidence of a previous full course of lectures at a regular college, eight years of reputable practice, a copy of his written examination by the Faculty of Columbus Medical College, a thesis in his own handwriting, and the recommendation of two medical gentlemen of West Virginia of high standing and character, etc., and after careful review of the case, they said there was no doubt as to his (Dent's) *qualification* and fitness for degree; that there was simply a technical 'irregularity,' *in this*, that the Board now required two full courses of lectures. In regard to the charges of graduating 'short time men,' these were without foundation, in the opinion of the Board."

A COLLEGE OF MIDWIFERY has been established in this city. The object of the institution is to give instruction to all desirous of learning the art of midwifery. There are, we are told, only two others of similar design in America.

The announcement says: "France and Germany have their schools and maternity hospitals, and no one can practise midwifery without a thorough course of training, passing a strict examination, and receiving a certificate or license. The opportunities for practical instruction in midwifery in this country are so limited that many of the graduates of the medical colleges begin practice without seeing a single case of obstetrics, and are sadly deficient in the details of this important branch."

The course of study lasts three months. Four evening lectures a week are given on anatomy, physiology, midwifery, puerperal diseases, and management of infants.

QUEBEC ANATOMY ACT.—The Quebec Government has recently brought in important amendments to the Anatomy Act, which will, it is hoped, put an end to body-snatching in the Dominion. Inspectors are to be appointed whose duty it will be to see that all unclaimed bodies in institutions receiving government aid are handed over to the schools, who shall pay ten dollars for

each body. The institutions are to notify the inspectors within twenty-four hours after the death of any friendless persons, and claimants must show relationship within the third degree.

HEALTH STATISTICS IN CANADA.—The Dominion Government has increased the appropriation for the purpose of collecting and utilizing health statistics, the sum of \$20,000, instead of \$10,000 as last year, having been placed in the estimates just brought before the House.

THE SANITARY COUNCIL OF THE MISSISSIPPI VALLEY.—At a meeting of this Council, April 4th, the following resolutions were passed:

First.—That a committee be appointed by the President of the Council to petition the President of the United States to place the \$100,000 epidemic fund in the hands of the National Board of Health for disbursement, in case its use is demanded.

Second.—That in case the National Board of Health is deprived of the power of making inspections of persons and freight, when demanded by the local doctors, health certificates issued under the supervision of representatives of the Sanitary Council of the Mississippi Valley shall be accepted as valid by the Boards of Health of the Mississippi Valley, provided that said inspections be carried on under the rules and regulations heretofore prescribed by the National Board of Health.

A JUDGMENT AGAINST THE UNITED STATES MEDICAL COLLEGE.—New York Supreme Court. Special Term. The People of the State of New York, plaintiffs, against Robert A. Gunn, Benjamin J. Stow, Paul W. Allen, Alexander Wilder, Thomas A. Granger, Mark Nivison, and Dennis E. Smith, defendants. Judgment, April 4, 1883.

This action having been brought to trial upon the issue of law raised by the plaintiffs' demurrer to the defendants' second defence contained in their answer herein, and beginning with the words, "Second, And for a further and separate defence," and ending at the demand for judgment; and the said demurrer having been, by order of February 5, 1883 (settled and filed March 12, 1883), sustained, with leave to defendants to answer over on payment of costs; and the costs having been taxed at \$108.13; and the order having provided further that unless the defendants pay said costs and amend their answer within twenty days, plaintiffs should have judgment absolute against defendants as for want of an answer; and the defendants having failed to pay said costs, or amend said answer, within the time aforesaid,

Now, on motion of Leslie W. Russell, Attorney-General, attorney for the plaintiffs, it is

Adjudged: That the said defendants are not and have not been incorporated as a medical college, with the franchises or powers of a medical college; and that the said United States Medical College, mentioned in the complaint, is not and never has been incorporated as a medical or surgical college, and does not possess the powers or franchises of a medical college,

And it is further adjudged: That the defendants, and each of them, and all persons acting with or under them or any of them, be and they hereby are enjoined and restrained from acting, or assuming to act, as an incorporated medical or surgical college, and from usurping or exercising the power, functions, or franchises of

an incorporated medical or surgical college; and from maintaining or assuming to maintain, for gain or otherwise, a medical or surgical college; and from granting diplomas or certificates of graduation to medical students or practitioners, purporting to be granted by a medical or surgical college; and that the plaintiffs, the People of the State of New York, recover of the defendants, Robert A. Gunn, Benjamin J. Stow, Paul W. Allen, Alexander Wilder, Thomas A. Granger, Mark Nivison, and Dennis E. Smith, the sum of one hundred and eight dollars, and thirteen cents costs and disbursements taxed as aforesaid; and that plaintiffs have execution therefor. (Endorsed, Filed April 4, 1883.) (A copy.)

Dr. Nagle, Deputy Register of Vital Statistics, has instructed the clerks in the Bureau of Vital Statistics to reject all death certificates signed by graduates of that college.

DISCIPLINING A DOCTOR FOR PRODUCING ABORTION.—The New Haven Medical Association has taken steps to expel Dr. E. L. R. Thomson on account of his connection with a case in the city court, in which he is charged with procuring an abortion. The statements made by his counsel, Col. Dexter R. Wright, claiming that there was not a father in New Haven who would not be willing that an abortion should be performed on his daughter to save her from shame and trouble, and that he would have no difficulty in finding physicians to perform the operation were strongly resented. The Prudential Committee claim that if Dr. Thomson is allowed to remain in the society it would be a tacit support of him.

DISTRIBUTION OF THE EXCISE MONEY TO THE MEDICAL CHARITIES.—The sum of \$35,430 from the Excise Fund has been assigned to the different charities of the city. The hospitals get between one and five thousand dollars each.

NURSES' TRAINING SCHOOL OF THE NEW YORK HOSPITAL.—The Commencement exercises of the graduating class of the Training School for Nurses attached to the New York Hospital were given April 5th in the lecture-room of the institution. This was the first Commencement of the school, which has been in successful operation since 1877, and the exercises were attended by a number of the friends of the pupils and of the hospital. The school numbers twenty-six pupils, of whom nine were graduated.

A BILL TO ESTABLISH A DEPARTMENT OF ECLECTIC MEDICINE in the University of Michigan has been introduced in the Legislature. Should it pass, that most catholic university will have a triple set of therapeutical professors.

ATTEMPT TO ROB A PHYSICIAN.—Dr. Patrick H. Flood, one of the oldest and wealthiest physicians of Elmira, N. Y., was knocked on the head in front of his own gate last Tuesday night, and would have been robbed but for his pluck and vitality, even under the stupefying effects of the blows. The robbers escaped, and there is no clue to their identity.

DR. HAVREMANN, a young physician residing in Rostock, has been appointed special physician to the Queen of Madagascar.

THE UTICA INSANE ASYLUM is being investigated again by a committee from the State Assembly.

DEATH OF DR. JOHN DAVIS.—Dr. John Davis, one of the oldest physicians of the city, died recently in his eighty-second year. Dr. Davis graduated from the College of Physicians and Surgeons in 1823. He had practised in this city and Brooklyn for fifty-five years.

MME. SCALCHI is staying while in New York with Dr. Louis Elsberg and his family, who are old friends of the great contralto.

CHICAGO MEDICAL SOCIETY.—The following officers were elected for the ensuing year: *President*, Dr. D. W. Graham; *First Vice-President*, Dr. R. G. Bogue; *Second Vice-President*, Dr. R. Park; *Secretary*, Dr. L. H. Montgomery; *Treasurer*, Dr. E. F. Ingals.

PROFESSOR CHARCOT has been elected an honorary member of the Royal Irish Academy on account of his important researches in pathology and physiology.

CAMBRIDGE UNIVERSITY.—England is gradually developing a medical school. Funds have been supplied for the Physiological Chair, occupied by Dr. Michael Foster. Dr. Humphrey has accepted the Chair of Surgery without stipend, leaving vacant an endowed Chair of Anatomy, which will soon be filled.

THE ORKNEY ISLANDS are at present suffering from a wide-spread and unwonted epidemic of measles.

Reviews and Notices.

A MANUAL OF THE PRACTICE OF MEDICINE. Designed for the Use of Students and the General Practitioner. By HENRY C. MOIR, M.D. Second Edition. 12mo, pp. 455. New York: James H. Belding.

THE second edition of this admirable little work has been very carefully revised, and several portions of it have been entirely rewritten. We take occasion to repeat our good opinion of the work, considering it, as we do, one of the best condensations of the theory and practice of medicine that has been published. The more it is known the better will it be appreciated.

POCKET THERAPEUTICS AND DOSE-BOOK. By MORSE STEWART, M.D. Third Edition. Revised and enlarged, pp. 240. Detroit: Geo. D. Stewart & Co.

THIS little work, now in its third edition, hardly needs any special comment. We believe it will be found useful, and can recommend it, both to the student and practitioner.

A PRACTICAL TREATISE ON THE DISEASES OF THE UTERUS, OVARIES, AND FALLOPIAN TUBES. By A. COURTY, Professor of Clinical Surgery, Montpellier, France. Translated by AGNES M'LAREN, M.D., M. K.Q.C.P.I. With a preface by J. MATHEWS DUNCAN, M.D. Philadelphia: P. Blakiston, Son & Co. 1883.

COURTY's gynecology has been long familiar to the French as one of the ablest exponents of that branch of medicine. It is now made accessible to the English reading portion of the profession. The present is a good translation of the third edition of Courty's treatise, and may be said to compare favorably with the works of Barnes, Thomas, Emmet, and others. It can scarcely hope, however, to replace the volumes just mentioned, being more valuable to the specialist desirous of becoming familiar with Gallic methods, than the general practitioner in want of precise directions for daily use.

The introductory chapter of the work contains a good account of the anatomy, physiology, and teratology of

the female generative organs. The remaining chapters are divided into two parts—the first dealing with uterine diseases in general, and the second being devoted to their special and detailed consideration. We regret to find no description of that frequent class of diseases affecting the external organs of generation and the vagina. A work already extending to 802 pages might be profitably made complete by devoting some space to a discussion of the diseases of the external parts.

Laceration of the cervix does not appear to have engaged Courty's attention, a fact which the American reader will be sure to deplore. In general, the author's views on pathology are sound, and his therapeutical recommendations are practical and rational. We are pleased to find him quite emphatic about the great value of constitutional measures, while he does not underestimate the importance of local treatment. The translator is to be congratulated on the fidelity with which her part of the work has been accomplished. In conclusion we may repeat that no specialist should be without this work; but the student and general practitioner will scarcely need it.

LEGAL MEDICINE. By CHARLES MEYMOTT TIDY, M.B., F.C.S. Vol. I. Philadelphia: Henry C. Lea's Son & Co. 1882. Also, in two volumes, Wood's Medical Library. New York: Wm. Wood & Co. 1882.

THIS work is intended to be a comprehensive treatise on the branches of legal medicine. The present volume takes up the following subjects: Evidence, the Signs of Death, the Post-Mortem, Sex, Monstrosities, Hermaphroditism, Expectation of Life, Presumption of Death and Survivorship, Heat and Cold, Burns, Lightning, Explosives, Starvation.

To treat all these matters properly requires no small degree of research, knowledge, and judgment. The writer must not only be familiar with their physiology, pathology, and chemistry, but also have a good degree of legal knowledge. Dr. Tidy has shown that he is competent for the task so far, however, and has produced a volume which in scope and accuracy has no equal in the English language.

The plan of the work is excellent. The author has collected a very large number of illustrative cases, but has placed them at the end of the chapters instead of interpolating, as is the custom, in the text. This lightens the labor of reading and makes it easier to grasp the subject. There are many subdivisions and tables, which add to the intelligibility and clearness of the discussions.

The author shows an acquaintance with foreign literature, but he quotes less extensively from German works than could be desired, seeing that Germany has done the most scientific work in this particular field.

The book really deserves an extended analysis, but our space forbids this. An enumeration of the subheads in the chapter on "The Signs of and the Appearances Produced by Death" will show, however, how elaborately each topic has been studied. This chapter begins with a definition of death, somatic and molecular, then follow the titles Premature Burial, and The Circumstances under which the Medical Jurist may be called upon to Certify as to the Reality of Death. Under heading of "Signs of Death" we find the following: 1, The entire and continuous cessation of the heart's action, and 2, of respiration; 3, insensibility and loss of power to move; 4, certain minor signs of death; 5, changes in and about the eye; 6, changes in the temperature of the body; 7, changes in the muscles and in the general condition of the body after death.

The subjects of cadaveric ecchymoses, putrefaction, formation of adipocere, and mummification of bodies conclude the chapter, to which are appended many illustrative cases.

Dr. Tidy's work shows the very wide range of matters upon which legal medicine touches. It will be especially acceptable to medical practitioners at the present time, when interest in forensic medicine is increasing.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 5, 1883.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Corresponding Secretary, DR. J. G. ADAMS, announced the death of Brigadier-General Joseph E. Barnes, recently Surgeon-General of the United States, and Baron Jules Cloquet, of Paris, France.

The Statistical Secretary, DR. F. V. WHITE, announced the death of William H. Van Buren, M.D., LL.D.

DR. E. L. KEYES then read

A MEMOIR OF W. H. VAN BUREN, M.D., LL.D.,

in which he paid an eloquent and just tribute of respect to the dignified bearing, the gentlemanly deportment, the scholarly acquirements, the professional skill, and profound judgment of his grand old master and enduring friend.

DR. AUSTIN FLINT, JR., in behalf of Dr. Austin Flint, unavoidably detained from being present, offered resolutions expressing admiration of his character as a teacher, a writer, and a gentleman, and of heartfelt sympathy for the family of the deceased.

DR. LEWIS A. SAYRE, prevented by sickness from the privilege of seconding the resolution, sent a letter, which contained a touching reference to the sterling worth of his departed colleague.

DR. ALFRED C. POST, associated for many years with Professor Van Buren in the Medical Department of the University of the City of New York, took great pleasure in seconding the resolutions offered by Dr. Flint, and fully endorsed the eminently appropriate remarks made by Dr. Keyes. As a gentleman, a scholar, a teacher, and an operator, the deceased had left a name so distinguished that no one could be looked upon as his superior, and but few could be regarded as his equal.

THE PRESIDENT remarked that, having listened to the beautiful eulogy which had been read, the resolutions offered, and the remarks made by the gentlemen who had seconded them, he felt incompetent to add anything except to express the feeling that all must be heartily in accord with what had been said with regard to our departed Fellow.

The resolutions were unanimously adopted.

DR. BEVERLEY ROBINSON then read a paper entitled

A CLINICAL STUDY OF CAFFEINE AND CONVALLARIA MAJALIS AS CARDIAC TONICS.

The author of the paper gave a *résumé* of the literature of the subject, the views held concerning the physiological action of the drug, and added an extensive clinical contribution. The clinical histories of several cases, with post-mortem conditions, were referred to as having already appeared in the proceedings of the New York Pathological Society, published in THE MEDICAL RECORD.

THE PRESIDENT related the histories of two cases, and raised the question whether the effect produced by this remedy is entirely due to its power as a cardiac tonic, or whether it might not have another property, which is perhaps as useful, but which, so far as he had observed, had not been mentioned by any writer.

CASE 1.—Five weeks ago he was called to see a gentleman who was in a very feeble condition, but the only evidence of disease which he was able to detect was a general failure of nerve-power and loss of appetite and strength. Any exercise caused shortness of breath, and at times he suffered from a sense of suffocation, with palpitation and a feeling of terror. When an exacerbation came on the patient was ashy white, very restless, anxious, and alarmed, and there was coldness of the ex-

tremities. Careful examination, made not only by himself but by several eminent physicians in cities through which the patient had been travelling, failed to discover either cardiac, pulmonary, or renal disease. The patient had profound mental depression on account of a family affliction. It was noticeable, however, that during the periods of his greatest distress there was no marked feebleness of the pulse. Six drops of convallaria were prescribed to be taken every three hours. On the evening of the same day, six or eight hours having elapsed, the patient expressed himself as feeling very much better, and on the following day as being in the most comfortable condition he had been in for two months.

CASE II.—A widow had an attack of bronchitis accompanied by very violent and persistent cough. Nervous prostration was very great, attended by apprehension, inability to get her breath, palpitation, etc., *but there was no marked weakness of the cardiac impulse.* Convallaria was prescribed and the benefit which followed was even more marked than that shown in the first case.

The question was, Is it not a vasomotor stimulant?

DR. F. P. KINNICUTT remarked that his observations, also, made largely in St. Luke's Hospital, corroborated essentially those reported by Dr. Robinson. The diuretic effect of the drug, however, he had not noticed as being so marked as stated by the author of the paper. He thought that further experiments were necessary to determine the exact *modus operandi* of the remedy. He also regarded as still an unsettled question whether palpitation depends on exhaustion of the vagi or of the cardio-inhibitory apparatus.

DR. A. A. SMITH'S experience concerning the diuretic power of the drug accorded with that expressed by Dr. Robinson.

It had seemed to him that when cardiac hypertrophy was present the remedy was not indicated. In chronic renal disease, with cardiac hypertrophy, according to his observations, it aggravates the symptoms. In cases of enlargement of the heart in which dilatation predominates, it serves a very good purpose. He was not, however, prepared at present to give up digitalis and substitute convallaria. Nor was he quite sure the experiments of Ott had not demonstrated that it does not act through the pneumogastriacs.

Dr. Smith then referred to four well-marked cases of

PULMONARY ŒDEMA COMPLICATING PNEUMONIA,

occurring in his service at Bellevue Hospital, and which illustrated the good results that possibly might follow the administration of convallaria. Three patients received a hypodermic injection, containing ten minims of the fluid extract of the root of convallaria with one two-hundredth of a grain of sulphate of atropia, repeated every half hour, and all recovered. The fourth case was one of pulmonary Œdema complicating pneumonia, occurring in a patient suffering from Bright's disease, and it terminated fatally.

He had seen better results follow the use of hypodermics of one two-hundredth of a grain of sulphate of atropia than by the adoption of any other plan of treatment, and therefore was unable to say exactly how much the recovery in the three cases reported depended upon the effect produced by the convallaria; the combination, however, was a happy one.

DR. SMITH did not think that the drug acted as a direct respiratory stimulant, as does belladonna and strychnia, but that it probably acts through the circulatory system. However, on account of the difficulty of obtaining preparations of uniform strength, and for other reasons, he regarded it as important to be exceedingly careful concerning accepting conclusions with reference to the way in which the drug produces its effects, and precisely what those effects are.

DR. ROBINSON, in closing the discussion, said that he had not had cases which made him feel that possibly in convallaria we possessed a special stimulant to the vasomotor system.

On motion by DR. J. C. PETERS, the President was empowered to appoint a committee of five to make investigations concerning scarlet fever in horses.

The Academy then adjourned.

SECTION IN PRACTICE OF MEDICINE.

Stated Meeting, March 20, 1883.

EDWARD G. JANEWAY, M.D., CHAIRMAN.

(Continued from p. 359.)

DELIRIUM WITH EMPYEMA.

A CASE had lately come under his observation which presented some interesting and rather remarkable features. It was one of a series of cases of empyema. The patient was admitted to Bellevue Hospital and assigned to the insane pavilion as a case of acute mania. His wife said that he was apparently perfectly well until the night before admission, when she found him against the door with his head in his arms and screaming out, "father," "mother," "God," etc., and saying "they are going to kill me." Previous to that time he had been able to work and was in his usual health. The history seemed to be a rather straightforward one of mental aberration, and perhaps independent of any definite cause. The point of interest was that his left side was one-half an inch larger than the right, the apex-beat of the heart was two inches to the right of the median line, and there were well-marked evidences of effusion into the left pleural cavity. The hypodermic needle was introduced and pus was obtained. The patient, therefore, was suffering from empyema, and he had been taken suddenly with acute mania and without fever. Under the influence of hyosciamin and morphine he quieted down somewhat and had some sleep, and then Dr. Janeway attempted aspiration. His plan of treatment in such cases is, first, to aspirate the chest, and afterward, if necessary, to make a free incision. This led to the remark that he made it an absolute rule not to give anæsthetics for making an incision into the chest, as he believed it to be a most dangerous practice. In this case he experienced considerable difficulty in introducing the needle, and obtained only about twelve ounces of pus, for the reason that the fluid was so thick that it did not flow through the canula. On examining it microscopically its thickness was easily explained, and was due to two things: First, the large number of pus-cells; and, second, to the presence of little lumps of fibrin, equivalent in size to about six or eight pus-corpuscles. On the next day after the aspiration hydropneumo-thorax developed, and then followed rapidly a septic process. Five days after the operation Dr. Janeway made a free incision into the chest, and after washing out the cavity with a weak carbolyzed solution the patient's temperature fell to normal. So far, however, his mental condition had not markedly improved. The time at which his mental condition seemed to be the best was shortly after the occurrence of the pneumo-thorax.

Another interesting point in this case was the inability to say from the history when this process began. It was found, after considerable inquiry, that five years ago he was sick for about nine months, first in the hospital, where he was treated without benefit, and that he was short of breath, etc., and that he was then taken home and soon after spat up very large quantities of matter which gave him a great deal of relief. Dr. Janeway regarded it as possible that that process might have continued up to the present time, and perhaps was the original source of the empyema. One circumstance which pointed somewhat in that direction was the fact that the chest did not sink in after the free incision, the heart still remained displaced, and at no time had the pulse been very rapid, nor had the respiration been very hurried. In one case of empyema, much more marked than the one just related, the disease had existed probably for a year and a half before it came under observation, and the heart was displaced to the left. In that case for days

there was no elevation of temperature, and yet he removed two hundred and six ounces of pus at three sittings. A little further inquiry made it somewhat apparent that the disease dated as far back as three years. In that instance it was decided to diminish, if possible, the size of the pleural cavity, and he made a free incision. The patient has had no fever except on two occasions during the entire period, and the chest is now on the right side one and a half inch smaller than it was, although it is still about two inches larger than on the left side. There has been no accumulation of pus. In this case there was absence of those phenomena which are supposed to indicate the development of purulent pleurisy, but the symptoms throughout had been rather those of serous effusion. There had been an entire absence of elevation of temperature and sweating.

EXPLORATORY PUNCTURE WITH THE HYPODERMIC NEEDLE.

DR. JANEWAY remarked that, recently, German writers had brought forward the use of the hypodermic needle as a new means of making the exploratory puncture in cases of pleuritic effusion. This practice, however, he had followed during the last ten or twelve years, and it had also been freely adopted by others in this country. He believed that there was no danger in using the hypodermic needle if it was properly cleansed, and his rule was always to wash it thoroughly with warm water, and then with a strong carbolic solution, before introducing it into the chest.

DR. GIBNEY asked the Chairman if he attributed the delirium to the presence of pus in the pleural cavity.

The CHAIRMAN replied that the empyema had its influence in producing a deterioration of health, and in that way might be regarded as the cause of the delirium, the same as diseases of organs constitute causes of insanity.

DR. GIBNEY asked if delirium was not more likely to be an accompaniment of acute processes than of chronic.

The CHAIRMAN replied that it occurred very frequently in chronic affections with more or less anæmia.

DR. POST remarked that delirium is a common symptom in thoracic affections, especially in young children.

The CHAIRMAN remarked that, of course, cerebral abscess, embolism, and meningitis were to be excluded in making up an opinion concerning any given case.

DR. PUTZEL asked the Chairman if he had had any pathological experience with regard to the lesions of the mild chronic mania of Bright's disease.

The CHAIRMAN replied that there were lesions in these cases, such as peri-arterial thickening, œdema of the brain, and, as a result of the mixed process, there might be more or less anæmia of the brain. These conditions would in part account for the delirium.

DR. PUTZEL remarked that he had one case in which there was chronic mania lasting several months, and at the autopsy nothing whatever could be found to explain it.

DR. POST remarked, with reference to cleansing the hypodermic needle, that the method recommended by Dr. Squibb was a most efficient one, namely, to pass it through the flame of a spirit lamp or Bunsen burner.

A CASE FOR DIAGNOSIS.

DR. PUTZEL read the history of a case and submitted it for diagnosis. Joseph J—, fifty-nine years of age, a laborer, with unimportant previous or family history, had rheumatism (?) three years ago affecting the ankles and lasting three days. Twenty-five years ago he fell down stairs, and as the result of the injury received he was in bed ten weeks, was out of his mind for three months, and since that time has been easily excited, especially easily affected by drink, has had poor memory, but no headache or other symptoms, except more or less pain in the cervical spine.

In March, 1882, he went to bed all right, but his wife found him in a convulsion in the middle of the night, his body and legs twitching, but the arms being quiet. He

frothed at the mouth, and remained unconscious for an hour, with the mouth closed and moaning continuously. About fifteen minutes afterward he vomited and purged once. As soon as he regained consciousness he complained of pain in the shoulders and arms, and cried out with pain whenever he attempted to move the upper limbs. There was no pain in the lower limbs, which became very much swollen six weeks later. The upper limbs swelled at once from the shoulders to the wrists, and about two weeks afterward the arms turned black and remained so nearly two months. The pain which he had suffered in the cervical spine was relieved. There was no bladder trouble.

November 22, 1882.—Opacity of the right cornea due to injury. Eyesight normal in the left eye. Hearing approximately normal. Motion and sensation in the face normal. The left deltoid muscle is a little less full than the right. When the limb is directed forward he can raise it to a horizontal, but when it is directed outward, only to an angle of about thirty-five degrees. The head of the left humerus is very much enlarged, especially posteriorly. There are no sensory disturbances, and only very slight paresis of the other muscles of this limb. The right deltoid is apparently normal; shoulder movements freer than in the other limb. Anteriorly the limb can be raised a little above the horizontal, and outwardly above forty-five degrees. Enlargement of the head of the humerus very marked, especially posteriorly, where it simulates dislocation. Sensation normal. Other movements of the arm very good, although not quite so strong as before the attack. A sensation of coarse grating is obtained on motion in each shoulder-joint.

Six weeks ago there was considerable atrophy of the deltoids, and the other movements of the arms were considerably weaker than at present. The faradic excitability of the deltoids was slightly diminished (probably from the atrophy).

EPILEPSY FOLLOWING CEREBRAL CONCUSSION.

The CHAIRMAN directed attention to the fact that injuries of the character of that received in Dr. Putzel's case are not infrequently followed, after the lapse of a considerable period of time, by some cerebral disturbance. During the last year he had seen cases in which epilepsy had developed *three months, six months, three years, and six years* after the receipt of an injury which was probably the cause of the convulsive affection, no other cause being ascertained. He had been especially struck, with reference to such cases, by the fact that railroad companies desire a certificate from the person injured and with whom they settle, that the person so injured is absolutely well, and so worded that it looks forward to the cutting off of any compensation for possible future disturbance. He thought that medical men in giving certificates should, for their own interests, if for nothing else, be guarded in expressing an opinion beyond the fact that "such person, so far as present appearances go, is well, but that the future must be uncertain for at least one year—perhaps much longer."

Dr. Post thought it might be difficult to make the evidence strong enough to convince a jury that such remote consequences were the result of the injury. It might be regarded as probable, but not proved. If, however, there had been even slight disturbance, such as headache or other nervous manifestations, occurring at short intervals and referable to the injury, he thought we might fairly attribute the more grave phenomena to the same cause.

THE USE OF A BIVALVE ANAL SPECULUM TO FACILITATE CATHETERISM.

Dr. Post was requested by Dr. Gouverneur M. Smith to see in his service at the Presbyterian Hospital a man who was in the advanced stage of Bright's disease, and was unable to pass his water freely on account of the enormous œdematous distention of the prepuce. Nu-

merous punctures were made to evacuate the fluid from the cellular tissue, but he was unable to find the urethra. He then resorted to the expedient of introducing a small bivalve anal speculum into the preputial opening and carrying it down and dilating the tissues sufficiently to permit the introduction of a catheter.

The Section then adjourned.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 2, 1883.

JAMES B. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

CASE OF MASTOID DISEASE ILLUSTRATIVE OF TREATMENT AND CURE WITHOUT RESORT TO TREPHINE.

Dr. SEXTON, in presenting this case, hoped that this Society, so largely composed of practitioners who saw much of disease in general, would find it not without interest, inasmuch as it was a case in which the treatment adopted differed very widely from that generally in vogue. He thought that the mastoid was much too frequently trephined in these cases, and were one to estimate the value of the operation by the current literature of the subject he feared that we must conclude that fatal results had not been lessened by such treatment, and in some instances it even appeared that aggravation had resulted. In a large number of such cases occurring in his own practice he had not found the operation necessary.

The case had been referred to him by Dr. Weisse, on October 3, 1882. The patient came to this country from Ireland two years before the attack, and ever since her arrival had been subject to menstrual irregularities. She was found by Dr. Sexton to be suffering from an attack of purulent inflammation of the left middle ear and of the pneumatic cells of the mastoid process, consequent upon a severe cold in the head, contracted in March, 1882.

She is a tall brunette, twenty-four years of age, and weighs one hundred and forty pounds. Her mother probably died of consumption, but her own health has been pretty good until of late. Her condition was, when first seen, one of extreme depression, her complexion was sallow, the eyes were heavy, and the tongue coated. Her appetite was not good, and owing to the painfulness of mastication she was limited to soft or fluid foods.

The patient for a considerable time had been subject to naso-pharyngeal catarrh of the dry variety, with a tendency to ozena—dark greenish crusts forming in the upper pharynx, which were removed by persistent hawking every few days.

Altogether she presented the appearance of a very sick person, too weak, indeed, to ascend a flight of stairs without resting. Were it not for the aid given by her sister she could not keep up with her work as waitress, and she now fears she will have to give it up altogether. She had been seen by several physicians, the treatment consisting for the most part in the usual routine of syringing the ear and the introduction of powders into the external auditory canal. During the time she was so great a sufferer the ear discharged "off and on"—the secretions which accumulated in the tympanum every few days giving rise to painful distention.

That the patient had been long subject to aural catarrh was shown by the lustreless, porcelain-looking membrana tympani of the right ear. The left external auditory canal was found to be somewhat narrowed at the inner end from periosteal inflammation, which also affected the tempero-maxillary articulation, thus giving rise to the painfulness experienced in mastication. The left membrana tympani was inflamed and fleshy in appearance, and there were three perforations, one in front of, and one posterior to the short process (both in the membrana flaccidi) and one in the lower segment of the membrane. From each one of these perforations sprung a polypoid growth

the size of a very small pea. A slight, greenish colored, thick, purulent discharge existed.

Hearing was not greatly affected in the right ear, but she could hear a loud voice only in the left. At no time was tinnitus aurium a marked feature, although the voice was autophanous.

For the past two months there had been pain referred by the patient to the left side of the neck, and she was observed to hold the head very rigidly, inclining it to that side, motion being painful.

The integument over the mastoid was of a dark-red color; the tissues were considerably swollen, the prominence of the apex, owing to the extension of the swelling down the neck, being lost. During the past few days there had been pain in the neck just below the occiput, and higher up, toward the vertex, pressure could not be well borne.

The pains in the mastoid had been steady from the first, but during the past month they had much increased, and a dull, heavy pain is now constantly experienced. It is worthy of note that during the exacerbations of pain experienced in the ear, from retained secretions, the left cheek became flushed and moving the head extremely painful. There was a decidedly bad odor about the patient's ear, such as is sometimes experienced when carious bone is present.

The treatment adopted was the sulphurated lime, in small doses, in the form of hepar sulphur, and the tincture of aconite. The former was given every two or three hours at first, and the latter in teaspoonful doses of a solution consisting of a few drops of the tincture in four ounces of water. Locally, powdered boracic acid was lightly applied.

On the next day, October 4th, the patient reported that she had not rested so well for the past three months. She had experienced no pain excepting in the region down along the sterno-mastoid muscle. The three polypi were removed at this visit, one at a time, with my own snare. They were very soft, and the pedicles were slender. After their removal the membrane presented a smooth surface. During the first week the improvement of the patient was very marked; the purulent discharge became thinner and the polypi showed no disposition to return, although there was slight pouting. The appetite improved, mastication was easy, and the patient was more comfortable. Local applications of tincture of calendula were now made to the drumhead daily. Swelling, tenderness, and purplish redness of the skin over the mastoid remained. During the first month's treatment, improvement continued, although the discharge was variable. Fluctuation, limited to a small area over the mastoid was now found to be present, and an incision less than half an inch long was made down to the bone on a level with the external auditory canal. In a day or two a slight purulent discharge was established, and the running from the canal of the ear became less. The wound was carefully probed on this and subsequent occasions, and although some roughness of the bone was seemingly felt, no sinus leading through the cortex of the mastoid and giving exit to the discharge which evidently came from the mastoid cells, was ever found. The wound was soon filled with redundant granulation-tissue, which was for a long time elevated slightly above the surface. At one time the hepar sulphur was withheld for a few days, but the patient did not continue to improve until it was again renewed, and subsequently calcium sulphide was substituted in somewhat larger doses.

During the month of November the case slowly improved. The membrana tympani began to clear up, the nipples upon its surface becoming daily smaller. The discharge from the mastoid, at no time free, was less and irregular, sometimes ceasing entirely for a day or two. The discharge from the external auditory canal was almost absent.

During the month of December the treatment was continued, but the doses of the calcium sulphide were

given less frequently. Discharge from the external auditory canal ceased entirely about December 20th. At this time, when the perforations had closed and the intratympanic structures were clearing up, the flexible Eustachian catheter was daily employed to inflate the tympanum. There was only a little oozing of bloody serum now from the wound behind the auricle, and the incision had a tendency to close if let alone. There was great improvement in general health, the patient looking brighter. The hepar sulphur was again resumed, but was given in smaller doses. The membrane was almost entirely clear. During January the patient was feeling as well as ever, but early in February the mastoid incision, being occasionally the seat of irritation, was deepened with a knife. This was followed in a few days by a more free discharge, and on February 12th the wound closed altogether, and the patient was discharged cured.

Dr. Sexton drew the following conclusions from this case: *Otitis media purulenta*, occurring in subjects of ozena, is liable to assume a grave form, and extension to the mastoid cells is common. Such cases are also characterized by their chronicity. *Carious teeth and collections of tartar*, which give rise so often to irritation of the dental filaments of the fifth pair of nerves, were present in this case; in consequence of their reflex influence on the ear, such conditions should always be regarded as important etiological factors. *Uterine functional disturbance* was probably also a factor in this case, and had been in other cases also frequently observed by Dr. Sexton to react most unfavorably upon aural disease. *Hygienic treatment* had not been omitted, and was considered important in all cases. This patient had been required to take daily out-door exercise, although the weather during the time she was under observation was usually very inclement. The patient at no time entirely failed to attend to her work. *The dry method* which Dr. Sexton had adopted some eight years ago was practised in this case throughout. The few drops of tincture of calendula employed in the ear were not allowed to remain long in the canal, but were carefully removed by means of cotton-wool.

The employment of calcium sulphide in the case lessened pain, as it frequently does, and is by no means to be regarded as an inactive or "let alone" method, when its controlling influence over inflammatory processes about the ear is considered. The avoidance of anodynes, which, if given in large and repeated doses, derange the system, was considered advantageous.

Not the least interesting feature of the case was the behavior of the crusts, which eventually closed the perforations in the membrana tympani. They were observed to travel slowly toward the periphery of the membrane. The one in the anterior superior quadrant reached the walls of the canal within the first eight weeks; the one in the posterior superior quadrant was considerably slower, while the one on the lower segment did not disappear from the membrane until in the fifth month after the removal of the polypoid growths. Hearing in the affected ear was almost normal, and the autophonous voice had long since ceased to be experienced. No symptoms of ozena remained.

DR. GEORGE F. SHRADY remarked that the result was a very satisfactory one and served to prove the value of conservative treatment. He was not an otologist, but during the past four years, and since his intimate personal relations with a case that had attracted the attention of many of the leading specialists of the city, he had been much interested in the surgical management of the mastoid complications of otitis media. The patient, who was in a position to command the best talent which the city could afford, was the subject of a severe attack of inflammation of the middle ear. The disease ran its usual orthodox course, until finally symptoms of mastoid trouble manifested themselves, and trephining was proposed by one of the consultants as the only means of saving life. To this measure Dr. Shradý offered objections which were happily sustained by Dr. Roosa, the

gentleman having direct charge of the case, as well as by a majority of the other distinguished otologists and general surgeons subsequently added to the consultation. The patient finally recovered without the operation or the formation of an abscess externally, and in spite of the appearance of a formidable swelling of the neighboring soft parts. The good result in that case had made such an impression upon Dr. Shrady that he had become a convert to the conservative method of treatment. Since that time, through the kindness of Dr. Sexton and others, he had seen several cases of mastoid complication, some in which pus had already found its way externally, but in none had he felt called upon to advise the use of the trephine, or do more than increase the opening in the soft parts. In all of these there had been a perfect recovery. He did not presume to say that trephining of the mastoid was not a perfectly justifiable operation in very many instances, but that there was possibly not enough credit given by many surgeons to the wonderfully conservative power of nature in such as were generally looked upon as desperate cases.

DR. KINNICUTT was much interested in the good results claimed by the use of aconite in acute ear diseases in children. He also alluded to the prompt manner in which pain was relieved by the puncture of the drum-head.

Obituary.

JOSEPH K. BARNES, M.D., SURGEON-GENERAL, U. S. ARMY (RETIRED).

GENERAL JOSEPH K. BARNES, recently Surgeon-General of the United States Army, died in Washington April 5th, of Bright's disease. He was born in Philadelphia on July 21, 1817, and was in his sixty-sixth year. He studied medicine in the office of Dr. Thomas Harris, a celebrated physician of his generation, and attended lectures at the Medical Department of the University of Pennsylvania, where he was graduated with honor in the spring of 1838. The first year of his practice was spent as resident physician at the Blockley Hospital, where he laid the foundation for the distinction he afterward gained in the organization and management of the hospital system of the United States Army. His second year of professional work was devoted to the medical care of the poor in one of the northern districts of Philadelphia. On June 15, 1840, he was appointed an Assistant Surgeon in the army, and one month later was assigned to duty at the Military Academy at West Point. In November of the same year he was transferred to Florida, where he saw his first field service in Gen. Harney's famous expedition to the Everglades in the war against the Seminole Indians. He remained with Gen. Harney's command in Florida two years, and in 1842 was transferred to Fort Jessup, an old-time military station in Louisiana, where he served until its abandonment, four years later. At the breaking out of the Mexican war, in 1846, the young surgeon, then only twenty-nine years of age, was appointed chief medical officer of the cavalry brigade, and in that capacity he participated in every action of the war in either Gen. Taylor's or Gen. Scott's lines, excepting that at Buena Vista, and at the close of the hostilities was placed in charge of the general army hospital at Baton Rouge, La. For the next few years he rendered valuable service to the Government in organizing medical posts at various stations in Texas and throughout the West, acting for a short period as Medical Director of the Department of Oregon. He was assigned to duty at West Point again in 1854, and served there several years. In 1856 he received his commission as a Surgeon.

At the outbreak of the war of the rebellion Surgeon Barnes was stationed in Oregon, and was among the first officers to be called to Washington. In 1861 he was assigned to special duty in the office of the Surgeon-

General at Washington, where his experience in field and hospital service was of great value to the Government. Two years later he was promoted to be a Medical Inspector with the rank of Lieutenant-Colonel, and a few months afterward he was appointed Medical Inspector-General with the rank of Colonel. In September, 1863, he was made acting Surgeon-General, was promoted to fill the vacancy, with the rank of Brigadier-General. He served during the war with great honor, and in 1865 received the brevet rank of Major-General. He was the first physician called to the bedside of President Lincoln when he was assassinated, April 15, 1865, and had charge of the case until its fatal termination. On July 2, 1881, when the late President Garfield was shot, he was among the first physicians to be summoned to the White House, and served on the consulting board of physicians until the death of the President, giving the case his closest attention. He was placed on the retired list last year by the operation of the compulsory retirement law, and has since then been living quietly at his residence in Washington.

The General had a fine, erect military bearing. He was agreeable in his manners, and socially was a most attractive person. In his profession he stood deservedly high, and was universally respected by all who knew him.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 31, 1883, to April 7, 1883.

HAMMOND, JOHN F., Colonel and Surgeon. Granted leave of absence for six months on Surgeon's certificate of disability, with permission to go beyond sea. S. O. 75, par. 6, A. G. O., April 2, 1883.

HAMMOND, JOHN F., Colonel and Surgeon. To be relieved from duty in the Department of the East, and to report by letter to the Surgeon-General United States Army. S. O. 75, par. 7, A. G. O., April 2, 1883.

Official List of Changes of Stations and Duties of Medical Officers of the United States Marine Hospital Service, from January 1, 1883, to March 31, 1883.

BAILHACHE, P. H., Surgeon. Detailed as member of Board for the Examination of Officers of the Revenue Marine Service. March 27, 1883.

MURRAY, R. D., Surgeon. To proceed to Vicksburg, Miss., as Inspector. March 24, 1883.

PURVIANCE, GEORGE, Surgeon. To proceed to Cleveland, O., to investigate management of hospital. January 22, 1883. Granted leave of absence for seven days. February 8, 1883.

AUSTIN, H. W., Surgeon. To proceed to Gallipolis, O., as Inspector. January 9, 1883.

FISHER, J. C., Passed Assistant Surgeon. Detailed as member of Board for the Examination of Officers of the Revenue Marine Service. March 27, 1883.

CARTER, H. R., Passed Assistant Surgeon. To proceed to New Orleans, La., for temporary duty, thence to San Francisco, Cal., for duty. February 7, 1883.

PORTER, F. D., Passed Assistant Surgeon. Granted leave of absence for thirty days. February 10, 1883.

GUITERAS, JOHN, Assistant Surgeon. Granted leave of absence for thirty days. January 19, 1883.

WHEELER, W. A., Assistant Surgeon. To proceed to Chicago, Ill., for duty. January 27, 1883.

ARMSTRONG, S. T., Assistant Surgeon. To proceed to Key West, Fla., for temporary duty. February 1, 1883.

BENNETT, P. H., Assistant Surgeon. To proceed to Charleston, S. C., for temporary duty. February 19, 1883.

Resignation.

PORTER, F. D., Passed Assistant Surgeon. Resignation accepted, to take effect March 31, 1883. February 10, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 10, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
April 3, 1883.....	0	11	128	12	97	54	2	0
April 10, 1883.....	0	6	130	6	121	55	1	0
<i>Deaths.</i>								
April 3, 1883.....	1	6	29	12	25	21	4	0
April 10, 1883.....	0	5	15	6	16	23	1	0

Whole number of deaths for the week ending Saturday, April 7th, 746; of which 132 were from pneumonia.

THE RESULTS OF SECTION OF THE VAGUS UPON SHEEP.—Ellenberger has made some very interesting experiments to determine the effect of section of the pneumogastrics upon sheep. He found that after cutting the pneumogastric on one side only, no disturbance of heart, lungs, or stomach was observed. The general matter was not impaired. Ten weeks after the section the animals were killed. There appeared to be some thinning and atrophy of the muscular wall of the third and fourth stomach in the animal whose right vagus was cut, and a similar change in the first and second stomach of the animal whose left vagus was cut. When both vagi were cut the animals died in from twelve to twenty-six hours, except in one case, when life was prolonged for sixteen days. Death resulted in all cases from suffocation by stopping of air-passages. There was constantly observed: complete paralysis of the œsophagus, partial paralysis of the first and second stomachs, increased heart-beat up to 160 per minute, labored irregular and at first slower (12 to 16 per minute) respiration, and inability to regurgitate and chew the cud. It appears that the vagus sends motor nerve-fibres to the first and second stomachs, but that the third and fourth stomachs are enervated independently. The constant development of *tyimpanitis* as a result of paralysis of the vagus may have some practical significance.—*Journal of Com. Med.*

THE SEAT OF THE "MUSIC OF THE HEMISPHERES" IN THE DOG.—H. Munk thinks that he has located the centre of hearing in the cerebral cortex of the dog. And not only this, but he believes that different parts are devoted to the perception of different notes. This centre for sound-sensations is in the convolution near the apex of the post-sylvian fissure. The posterior parts appreciate the low notes, while the more anterior portions appreciate the higher notes.—*Journal of Comp. Med.*

CONGENITAL ABSENCE OF ONE KIDNEY.—Another recent case of this kind has been reported by Dr. Turbin, of Tiflis (*Deutsche Med. Zeit.*). He has collected eight similar cases from literature. That this may especially concern the surgeon is shown by a recent case from Czerny's clinic. That surgeon found it advisable to extirpate a kidney for disease, the operation being performed with his customary dexterity and skill. On the death of the patient some thirty-six hours later, it was first made known that the patient had had but one kidney, and that it had been removed. A similar case occurred in New York some time ago.

A CURIOUS EXPERIMENT.—The ease with which persons fall under hallucinations of special sense is illustrated by M. Yung, in a recent communication to the Helvetic Society of Sciences. The operator places eight cards on a table, in positions corresponding to forehead,

eyes, ears, nose, mouth, and chin; he pretends to "magnetize" them and also some person in the company, and then goes out, while the magnetized person is required to touch any one card. The operator, having returned, notes the action of a confederate, who scratches a part of his head corresponding to the card touched. Then he commences an innocent comedy, passing his hand carefully over the cards, and on reaching the touched card seeming to experience a strong shock. The observers are surprised, of course. One of them is then asked to go out and repeat the experiment. It is assumed that a certain card has been touched. Passing his hand over the cards, he indicates, in nine cases out of ten, a particular card as giving him a shock; and if the company be instructed to support his idea of that being the "correct card," he is confirmed in his illusion, which may be successfully repeated. Of 85 persons tried, M. Yung found only 9 who refused to indicate a card, not having experienced any sensation; 53 said they had exactly the sensation announced, and 23 described some different sensation.

THE EVERLASTING PILL.—The "everlasting pill," once a part of our ancestors' armamentarium, was composed of metallic antimony, and it was believed to have the property of purging as often as it was swallowed. This was economy in right earnest, for a single pill would serve a whole family during their lives, and might be transmitted as an heirloom to their posterity. We have heard of a lady, who having swallowed one of these pills, became seriously alarmed at its not passing. "Madame," said the physician, "fear not; it has already passed through a hundred patients without any difficulty."

THE QUESTION OF NATIONALITY has at last found its way into medicine. The French doctors in Nice are up in arms against their English and other foreign brethren established in that favored health resort. A general meeting of the former body has been held, at which protests were entered against the manner in which alien practitioners monopolize the most lucrative practice. Amongst other points which were urged, it was stated that many of the intruders are not qualified French physicians, and consequently have no right to practise anywhere in France.

CREDIT TO WHOM CREDIT IS DUE.—Philip Doddridge (1702-1751) spoke of nerve-stretching, and recommended it as a religious stimulant in his zeal and vigor in the Christian race.

"Awake my soul: stretch every nerve,
And press with vigor on."

MEDICAL PROFESSOR TO RAW STUDENT: "Where is the glottis?" "I don't know, sir. I think you put it on the shelf in the dissecting-room with the rest of your surgical instruments."

BLESSED IS THE COLLEGE, and especially the medical school, says the *Boston Medical and Surgical Journal*, which is so munificently endowed that it can fix its standard of scholarship independently of the necessity to make a living for itself; in fact, which can from the first adopt the position of the sought and not the seeker.

THE WATER-CLOSET'S DOOM.—An ingenious German has invented a plan for the manufacture of gas from human feces. These are decomposed in a retort by heat, the chief products being a light-yielding gas, carbonic acid, tar, oil, and ammonia. As in ordinary gas-works, the tar and oil are separated, and the light-yielding gas purified for use. There remain in the retorts the ash-constituents with a portion of carbon, which the inventor designates coke. The authority for this description, *Der Techniker*, informs its readers also that a Breslau hotel has already been successfully lighted by means of this novel and presumably economical gas.

JONATHAN HUTCHINSON'S ADVICE TO MEDICAL STUDENTS.—"If now I were to sum up in one sentence what I have been enforcing, it is this: The secret of all noble life lies in belief, and the characteristic of all noble minds in the vigor with which they believe that which is

true. Try to attain belief in the reality of all things ; so shall you never want for motives ; so shall you be able to live and work without hurry and without sloth. Finally, permit me to commend you this formula : Prize strength, love the beautiful, practise self-denial, and be patient."

A CANDID CRITICISM ON THE ACTION OF THE NEW YORK STATE MEDICAL SOCIETY.—We do not share in the opinions of those who see in this action (the vote of the New York State Medical Society) nothing but disaster to the profession. We do not believe that the teachings of the code of ethics are infallible, that its provisions should be accepted with unquestioned faith, and that any amendments thereto, or an abrogation of one or all of its provisions, would encourage quackery, disorganize the profession, and place it on a common level with all the isms and pathies of the age. We have more faith in the honesty and probity of the great body of men who compose the profession of this country, as exhibited from time immemorial in the performance of those imperfect obligations which the code does not reach and cannot enforce, than to believe for a moment that, if the entire code should be abolished, the old professional ship would lose her bearings and be dashed to pieces on the inhospitable shores of quackery. Therefore we are perfectly willing that our New York brethren shall try the merits of the new code, and if, as they believe, it will result in good to the profession and to humanity, the whole profession will ere long follow their example ; and if, on the other hand, it shall result, as has been predicted, in lowering the tone and dignity of the profession and the encouragement of quackery, we do not doubt but they will soon see their folly, repudiate the new code, and return to their first love, wiser if not better for their experience.—*Indiana Medical Journal*.

DIPHTHERIA IN FOWLS.—Dr. L. Roth, of Kitzingen, observed an epidemic of diphtheria in a flock of hens. It was caused by the slops from a room in which two children had been sick with diphtheria, being thrown upon the dung heap in the yard where the fowls were kept.

SOME LESSONS FROM THE SMALL-POX EPIDEMIC AT LOCKPORT, N. Y.—Dr. Walter J. Ransom, of Lockport, N. Y., sends us an account of the epidemic of small-pox at Lockport, N. Y., with some suggestive points relating thereto. The epidemic lasted from October, 1881, to January, 1882. It originated and was stopped in the following manner : "During the early part of October a woman was taken suddenly ill and died in a few days ; her sickness was pronounced 'gangrenous erysipelas complicated by acute eczema.' During her illness she was visited by numerous friends and acquaintances. A public funeral was had. Within different periods of time corresponding to the incubating stage of small-pox twelve of fifteen persons who had visited the patient came down with small-pox, and the result was that we had our hands full of just so many centres of contagion. We quarantined our cases according to the rules prescribed by the State Board of Health, and began the fight. In all we had about fifty-three cases. I suggested general vaccination as the remedy to prevent the spread of the disease, and submitted my plan to our local board, which was adopted, and they nobly sustained me in carrying it out. The plan was this : Our population is about fifteen thousand ; city divided into four wards ; two physicians to be appointed to each ward, they to be supplied with virus procured from the vaccine bureau of New York City, they to go from house to house, factory to factory, store to store, and office to office, and offer free vaccination to all. This was done, and not another case of small-pox did we have. Our vaccinating corps quilled about four thousand. The rule was to vaccinate all previously unprotected individuals, and all others who would consent to a re-vaccination who had not been vaccinated within seven or eight years."

One of the points of interest observed was the follow-

ing : "In one family, consisting of the parents and four children, two children too young to attend school, and never vaccinated, had confluent small-pox. The other children, vaccinated successfully during the summer term of school, escaped entirely. Parents, vaccinated years before, had varioloid. Another family, two adults, three children. Mother pregnant, six months advanced, protected by a previous vaccination, escaped entirely, and was subsequently delivered at full time of a healthy child. Her brother, boarding, unprotected, had confluent small-pox. In my experience the so-called partial working characterized by a red papule or macule was no protection. In many instances I saw the marked power of vaccine to protect, exemplified by the escape of all in the family who were vaccinated within three days of first exposure and in whose cases the vaccination worked. In my own case I escaped, and I was exposed, as far as man could be, without direct inoculation, for I delivered a woman who was prematurely confined and was dying with the disease at the period of secondary fever ; had retained placenta, which I removed.

"I say, palsied be the tongue that opposes vaccination."

SLOW PULSE.—Dr. W. T. Harris, of Brantford, Ontario, Canada, writes : "In one of the numbers of THE RECORD last summer, I observed a reference to a remarkably slow pulse, thirty-six per minute. Last October, I saw a gentleman in perfect health with a pulse of thirty-one per minute, and the same case I saw again last week, and found his pulse thirty-three per minute in the sitting posture. This man is sixty-eight years of age, and has always been perfectly healthy. He is a farmer residing in the vicinity of this city."

A LIST OF HEALTH OFFICERS OF THE PORT OF NEW YORK FROM 1784 TO 1884. Dr. Stephen Smith of this city writes : "While engaged in the preparation of a Report to the National Board of Health on the 'Origin and Growth of the Quarantine Systems of the United States,' I obtained from Mr. Ferno, the learned custodian of the colonial archives of the State of New York, a corrected list of the names and dates of appointment of all the Health Officers of the Port of New York. As the first appointment was made in 1784, and as the present Health Officer's term continues until 1874, the list comprises a century of Health Officers of this Port. At the same time, Mr. Ferno prepared lists of the Commissioners of Health, of Resident Physicians, and of the Health Officers of Albany and Hudson. I am not aware that these lists have ever been published."

Health Officers of the Port of New York : Charles McKnight, appointed May 12, 1784 ; Malachi Treat, January 10, 1792 ; William Pitt Smith, September 29, 1795 ; Richard Bailey, February 19, 1796 ; Isaac Ledyard, August 22, 1801 ; John R. B. Rodgers, October 5, 1803 ; Joseph Bailey, March 15, 1810 ; John R. B. Rodgers, February 19, 1811 ; Joseph Bailey, March 5, 1813 ; Benjamin De Witt, March 6, 1815 ; Joseph Bailey, February 4, 1820 ; John T. Harrison, April 24, 1823 ; John S. Westervelt, February 25, 1829 ; William Rockwell, February 10, 1836 ; A. Sidney Doan, February 14, 1840 ; Henry Van Hovenburgh, February 8, 1843 ; Alex. B. Whiting, January 28, 1848 ; A. Sidney Doan, April 4, 1850 ; Richard L. Morris, April 10, 1852 ; Henry E. Bartlett, April 21, 1854 ; Richard H. Thompson, April 21, 1855 ; Alex. N. Gann, April 6, 1859 ; John Swinburne, March 19, 1864 ; John M. Carnochan, January 27, 1870 ; S. O. Vanderpoel, February 28, 1872 ; William M. Smith, March 24, 1880.

Commissioners of Health under the Act of April 1, 1796 : Robert Bowne, Francis Childs, John Campbell, John B. Coles, William Robinson, Henry Will, John Murraysen, appointed April 9, 1796 ; William De Peyster, appointed September 30, 1796.

Act of February 10, 1797 : John Oothoudt, Jacob Abramse, Ezekiel Robins, appointed February 25, 1797 ;

Gabriel Furman, March 12, 1799, reappointed April 9, 1800; Edward Miller, appointed August 22, 1801; Gardner Jones, October 5, 1803; John H. Douglas, April 6, 1807; Gardner Jones, February 8, 1808; John H. Douglas, April 3, 1810; Gardner Jones, February 19, 1811; John Onderdonck, March 5, 1813; Samuel Torbert, March 6, 1815; Nicoll H. Dering, April 24, 1818; Peter S. Townsend, June 6, 1820; Jacob Dyckman, February 13, 1821; Richard L. Walker, April 11, 1823; Smith Cutter, April 22, 1828; James H. Hart, March 14, 1838; William Turner, March 14, 1840; Stephen R. Harris, February 8, 1843; Richard L. Morris, April 4, 1850.

Resident Physicians of the Port of New York (Act of February 25, 1799): James Tillary, appointed March 12, 1799; John B. R. Rodgers, March 27, 1802; Edward Millen, October 5, 1803; Joshua E. R. Birch, April 3, 1810; Edward Millen, February 19, 1811; J. E. R. Birch, March 5, 1813; Nicholas I. Quackenbos, March 6, 1815; David Hosack, June 6, 1820; N. I. Quackenbos, February 13, 1821; reappointed, April 24, 1823; Joseph Bailey, appointed February 4, 1826; James R. Manley, April 11, 1828; William James McNeven, April 9, 1840; John W. Francis, July 6, 1841; Alexander F. Vache, August 16, 1843; Seth Geer, January 21, 1848; Orid P. Wells, January 25, 1850.

Health Officers of Albany, N. Y.: Charles D. Cooper, appointed March 27, 1794; Christopher C. Yates, April 11, 1803; Peter Wendell, April 11, 1822; Barent P. Staats, July 3, 1832; John F. Townsend, March 10, 1840; Richard H. Thompson, January 15, 1849; John Swinburne, May 28, 1855.

Health Officers of Hudson, N. Y.: Joseph Hamilton, appointed October 3, 1803; Moses Younglove, February 9, 1809; Robert G. Frary (Tracy?), June 21, 1832.

A RAPIDLY SUCCESSFUL TREATMENT OF ERYSIPELAS is, according to Dr. Richard Barnwell (*Lancet*), the painting the part with white-lead paint. He reports five cases of traumatic erysipelas so treated, and one case of idiopathic erysipelas.

DOCTORS' DINNERS AND DOCTORS' WINES.—A writer in the *London World* discourses upon the difference between the preaching and the practice of London medical men: "As an M.D., Æsculapius cannot hear the name of wine or spirits mentioned without a shudder; but as Amphitryon, it is quite another thing. He is the most lavish of hosts, keeps an excellent cellar, and gives his guests of the best which it contains without stint. Doctors were surely never so nobly fond of seeing their friends at dinner as at the present moment. It is Hippocrates, Podalirius, Machaon, and others who make up the company of veritable Amphitryons. Politicians, diplomatists, poets, novelists, journalists, and even royalty meet round his pleasant and profuse board. A little of that Roman punch, you are surprised to hear, is indispensable after the clear turtle. A couple of glasses of Johannisberg is the minimum which it is safe to take with your fish. Then comes the question which champagne you will have, Pommery Greno or Perrier-Jouet—*brut* or only *sec*. Your astonishment increases as the banquet proceeds. Champagne—you can scarcely believe your ears as the sentiment is uttered—is the true drink of the statesman and the author; and champagne is not a wine which, if it is to be appreciated, can be sipped. If you had any superstitious idea that it was unwise to touch claret after dinner, you are entreated to emancipate yourself from it as soon as possible.

"Doctors' dinners have deservedly achieved a high place in the scale of London entertainments. And, indeed, so hospitable are the doctors, that it would really seem as if they did not wish their friends and patients to dine with any one except themselves. If you happen to feel a little out of sorts, and, on consulting your physician, mention that you have latterly been dining out a good deal, he shakes his head; and, while commencing with

the general proposition that alcohol is, under all circumstances, abominable—that for wine in any shape you should substitute cocoa, and milk, and beef-tea, and other slops—concedes you the indulgence of a couple of glasses of a remarkably thin hock at dinner. This wine is only to be purchased at one establishment in London; and of this Æsculapius gives you the address: your only chance of physical salvation lies in being constant to it. If you attend a dinner-party, a bottle of it must be your *vade mecum*. It looks somewhat odd to see a gentleman produce from his coat-pocket a flask of a fifth-rate Rhine vintage. You do not quite like the idea; but you are sternly informed that it must be done. You must obey the special mandate of your physician; and if you have not the courage to do this you had better decline the hospitality of your friends."

THE PROTECTIVE FUNCTION FOR ANIMALS OF THE SEMICIRCULAR CANALS OF THE EAR.—Necessity compels most of the higher animals, but especially wild animals, to be constantly on the alert, and the sense of hearing is of especial value in self-protection. Dr. P. McBride endeavors to prove the theory (which is not entirely new) that the semi-circular canals have an important function in this matter. Sudden sounds conveyed to the internal ear excite the nerve-fibres. These reflexly cause a sudden turning of the head in the direction of the noise. This action is seen when a deer is suddenly startled by a whistle. The other function of the semicircular canals relates probably to the sense of space. Stefin has recently asserted that the cells of Purkinje in the cerebellum were in close relation with the semicircular canals, so that when the latter are destroyed the former elements atrophy.—*Journ. of Comp. Med.*

SEAT OF "GOOD NATURE" AND INTELLIGENCE IN DOGS.—Goltz, by experiments upon dogs, shows that extensive and profound destruction of both vertex convolutions causes not only diminished intelligence, but also a remarkable change in their disposition. Harmless and good-natured dogs, after this operation become surly, quarrelsome, and violent. If the occipital lobes are damaged, the animals preserve their good-tempered character, but the intelligence is more seriously impaired.

A CASE FOR THERMOMETERS.—Dr. A. L. Cory, of Chicago, writes: "I desire to add my mite to the methods of preventing broken thermometers. Some years since I carried my thermometer-case loose in my pocket, and averaged a broken thermometer at least once in two weeks. Three years since I had constructed a case which contained a tongue depressor, an hypodermic syringe, with space for morphine powders, and a small bottle with the compressed hypodermic tablets. It takes little room, being only two inches wide, five and a half inches long, and three-fourths of an inch thick. I have carried it in my pocket now three years, and during that time have broken only one thermometer, and that I let slip from my fingers when shaking down the register. The case was made for me by E. H. Sargent & Co. of this city."

THE NEW YORK PHYSICIANS' MUTUAL AID ASSOCIATION.—The fourteenth annual report of this association shows a continued prosperity. The additions to the membership in the past year have been twenty-six, the deaths ten. The association has been able to give \$425 to the families of deceased members. In future it will be able to do more, for its permanent fund now amounts to over ten thousand dollars, and the interest upon it will hereafter be used.

We are glad to observe the success of this association, and would urge its claims upon the physicians of the city and neighborhood. Any member of the regular medical profession of the counties of New York, Kings, Queens, Richmond, and Westchester, in good health, and under seventy years of age, may be admitted.

A PURE ALKALOID OF GELSEMINUM has been obtained recently, and for the first time, by Mr. A. W. Gerrard, of the London Pharmaceutical Society.

CATARRHAL HEADACHES AND ALLIED AFFECTIONS.¹

By RICHARD C. BRANDEIS, M.D.,

PROFESSOR OF LARYNGOLOGY, RHINOLOGY, AND OTOTOLOGY, NEW YORK POLYCLINIC.

THERE is no class of disease which presents more varied types and greater difficulties in the differential diagnosis and treatment than that which is grouped under the generic name of headache. It is met with not only in nervous affections, but in almost every other form of disease, as in fever, in disturbances of the digestive organs, and in the most diverse inflammations of the head and adjacent parts.

As the caption of this paper shows, it is not my intention to enter into a consideration of all the various types of headache, but I wish to call your attention to those forms which, in my opinion, are due to the different diseases affecting the nasal and adjacent cavities.

If we bear in mind the fact that the nose has to perform a threefold function, we cannot but agree that a consideration of the relations which it bears to the system at large must be of great importance. The special function of the nose is to preside over the sense of smell; it plays a leading part in the process of respiration, since in health all the air taken into and expelled from the lungs, is intended to make its way through the nasal cavity. The voice is also dependent, in a great measure, upon the co-operation of the nasal cavity, inasmuch as it acts the part of a resonant chamber.

Nature has recognized the important rôle which the nasal cavity has to play in the general economy by placing it in the middle of the head and bringing it into direct communication with almost all the bones which enter into its construction. It is, as I hope to show you, in immediate relations with the cavities of the superior maxillary, the frontal, ethmoidal, and sphenoidal bones.

The nose consists, grossly, of two parts: first, the anterior prominent part, which is composed of bone and cartilage, with small muscles which slightly move the latter, and two orifices, the anterior nares, opening downward; and, secondly, of the two nasal fossæ. As the former part does not participate in the affections which we propose to consider, it is hardly necessary to enter into its anatomical details, as it contributes but little to the physiology or pathology of the parts under discussion.

The nasal fossæ are two cavities, placed one at each side of the median line, separated by the flat, vertical septum, part bony and part cartilaginous. The depth of the fossa from the upper to the lower wall is considerable, as is also the extent from before backward, or between the anterior and posterior nares. But the breadth from the outer to the inner wall is very limited, and is less at the upper than toward the lower part of the fossa, and in the middle than at the anterior or posterior openings. The roof of the nasal fossa is flat at its middle part, and sloped before and behind; it is formed in front by the inner surface of the nasal bones; behind by the body of the sphenoid, and in the middle by the horizontal or cribriform lamella of the ethmoid bone. The floor—smooth, concave from side to side, and formed by the palatal plates of the superior maxillary and palate bones—

extends backward and a little downward from the nares to the pharynx.

The internal wall, or septum narium, which extends from the roof to the floor of the cavity, is flat, almost vertical—although often deviating toward the left side—and composed of the perpendicular plate of the ethmoid bone, the vomer, and the nasal cartilage.

The outer wall of the cavity is formed by the ethmoid, superior maxillary, lachrymal, inferior turbinated, and palate bones. The posterior and inferior parts of this surface are marked by a number of inequalities, whilst the superior and anterior are comparatively even. In the latter situation may be observed, first, the smooth surface just mentioned, and secondly, passing downward and backward, three, and sometimes four-arched and convoluted bones, beneath which are grooves (meatus) leading from before backward. The superior turbinated, or spongy bone, is much shorter than the others, arises from the lateral plate of the ethmoid; beneath it is the superior meatus. The middle spongy bone, also arising from the ethmoid bone, overhangs the middle meatus. The inferior turbinated bone appears as if appended to the side of the superior maxillary and palate bones. Between it and the floor of the nasal cavity we have the inferior meatus.

To illustrate the relations which the nasal fossæ and the pneumatic cavities in the adjacent bones, which form their framework, bear to one another, I beg to show you a number of anatomical sections of the head, which I made a few years ago, according to Schalle's¹ method.

In specimen No. 1 I have cut away the external nose, the frontal bone, all of the superior maxilla of the right side, and on the left side have only left that part which forms the external wall of the corresponding nasal cavity. In order to show the position of the turbinated bones on the left side, I have removed the external nasal wall on the right, as well as the septum narium, excepting the nasal plate of the ethmoid.

If we look at the specimen in front, we see, above, the left frontal sinus, with a bristle passing downward through the infundibulum into the middle meatus. Looking downward, and near the roof of the cavity, on either side of the vomer, we see two foramina, which, leading upward and backward, pass into the sinuses situated in the body of the sphenoid bone. Looking at the left external wall of the cavity from the right, the short superior and the middle and inferior turbinated bones are brought into view. At the same time, farther back, the pharyngeal orifice of the left Eustachian tube can be seen.

In the second specimen, I have removed the frontal bone, the external nose, and the outer half of both of the superior maxillæ. I have, however, left the nasal fossæ and their component parts, as nearly as possible, intact. On the left side, we see the inner wall of the antrum of Highmore. We see this also on the right side, but find, near the upper and posterior border of the cavity, the foramen which connects it with the right nasal fossa, and which passes in through the middle meatus near the lower surface of the middle turbinated bone. In front, we see, above, the right frontal sinus, a bristle passed through the foramen which connects this cavity with the nose, and which enters the middle meatus just above and in front of the foramen which leads into the antrum of Highmore. Further down we see the right and left nasal fossæ, separated one from the other by the vertical septum,

¹ Read before the County Medical Society, March 26, 1883.

¹ Virchow's Archive, 1877.

which, however, in this instance, deviates somewhat to the right side. On either side of the septum we see, above, the middle turbinated, and below, the inferior turbinated bones. We can also see the inferior, middle, and superior meatuses of both sides. In this specimen the three cavities of the nose are very large; but I must call your attention to the fact that in the living subject they never attain this size, owing to the extreme vascularity of the mucous membrane lining the septum and the turbinated bones. This mucous membrane attains its greatest bulk on the inferior turbinated bone, where, according to Kohlrausch¹ and later observers, it forms a truly cavernous network, which in health attains a thickness of at least four millimetres between the periosteum and the lining membrane. This erectile tissue is sufficient to explain the transitory obstruction to nasal respiration which a sudden turgescence sometimes gives rise to, as well as the profuse mucous secretions which are common to acute and some chronic catarrhal conditions.

In the third dissection I have removed all the parts not directly connected with the nasal fossa. On the right side we again see the inner wall of the antrum of Highmore and the foramen which leads into the nasal fossa. It will be noted, however, that this foramen is not situated in the upper and posterior angle of the inner wall, but is seen near the anterior superior angle of the cavity. On the left side there is no salient point. Viewed from the front, the specimen shows, above, the two frontal sinuses, with bristles passing downward and backward through the infundibuli into the middle meatus on either side. Lower we see the septum narium and the two pairs of turbinated bones. In order to show the cavities of the nose, as well as those of the ethmoid and sphenoid bones, I have made two vertical sections through that part of the base of the skull formed by the frontal, ethmoid, and sphenoid bone, on either side of the median line. These sections pass downward into the nasal fossa on either side of the septum narium, and when the parts are held asunder we see the nasal cavities in their entirety. On the right side we see, above, two of the sphenoidal cells, below these the middle and inferior turbinated bones and the three longitudinal canals. We next see the septum narium and its component parts: the nasal plate of the ethmoid, the vomer, and the cartilage. On the outer wall of the left half of the specimen we have an excellent view of the cells contained in the ethmoid bone in front, and of the sphenoid bone behind. We can here see how the cavities of these two bones are connected, and in what manner they bear relation to the nasal cavity. Below we again see the turbinated bones, with their respective meatuses, and behind the inferior turbinated bone we have a fair view of the orifice of the Eustachian tube. We learn from this dissection that in the superior meatus there is a small orifice which leads into the posterior ethmoidal cells, and through them into the sphenoidal sinus.

In acute coryza we have, besides the lassitude, general malaise, and alternate chilliness and heat, more or less weight and pressure about the head, especially in the frontal region. On ocular inspection we find the nasal mucous membrane highly congested, and sometimes so swollen as to produce occlusion of the fossæ. The greater the obstruction the greater will be the sense of uneasiness about the forehead, which in some cases may reach such a degree as to cause the patient and surroundings considerable anxiety. I have seen instances where the agony was so great that fears were entertained that there might ensue a loss of reason.

This condition, however, generally endures only during the first stage or dryness of the nasal mucous membrane. As soon as the mucous discharges have fairly set in, a gradual amelioration of the symptom is usually observed.

The connection between the nasal cavity and the frontal sinus is very free by means of the anterior eth-

moidal cells and infundibulum. The sinuses in the frontal bone vary greatly in size, and in proportion to it will be the distress occasioned by any inflammatory condition which may be propagated to them from the nose. The membranous lining of these cavities is similar to that of the nasal fossæ. But, as Luschka¹ says, it is subject to certain modifications, which consist of a diminished thickness and a far less number of secreting glands than is found in the pituitary membrane. As long as the nasal mucous membrane is in an active state of inflammation, which is attended with a greater or less degree of swelling, the communication with the frontal sinus must be occluded. As soon as secretion sets in there must be an accumulation of fluid, which presses upon the anterior and posterior tables of bone forming the boundaries of the cavities, and as the pressure increases so will there be an increase of the pain. This may cease almost spontaneously as soon as the imprisoned fluid finds an exit through its natural passage, and if the inflammation subsides entirely no further discomfort need be felt.

In order to illustrate the causal connection between acute coryza and frontal pain, I will give a brief history of a case which was recently under my care:

Mr. Charles P—, aged twenty-seven, traveller, has been subjected to repeated violent attacks of colds, which manifested themselves chiefly by marked obstruction of the nasal passages and intense pain in the forehead, extending to both temples. This pain has, during recent attacks, been so severe that the patient was completely prostrated and unable to sleep in spite of the administration of the most powerful hypnotics. I found, on examination, that he had an unusually prominent brow and very protuberant superciliary ridges. On inspection, the mucous membrane covering the inferior turbinated bones was found to be so much swollen that the latter were in absolute contact with the septum narium on both sides. The entire surface of the forehead was painful to the touch, but the notches, through which the supraorbital nerves pass, were not more markedly tender. The entire mucous surface was dry and harsh, and touching it lightly with a probe caused considerable pain.

In order to stimulate the secretions, and thereby diminish the bulk of the mucous membrane, and restore the patency of the foramen leading to the frontal sinuses, I prescribed a small quantity of Hegar's fluid, with instructions that a few drops should be inhaled every hour until profuse secretion had set in. This fluid is composed as follows:

R. Acidi carbol. cryst.	3 j.
Alcohol fort.	3 iij.
Liq. ammoniæ fort.	3 j.
Aquæ destillat.	3 ij.

M.

This the patient employed five or six times, when a profuse mucous discharge appeared, accompanied by a gradual disappearance of the headache. The next morning he again visited me, and at that time, aside from a feeling of weariness, all discomfort had disappeared. The entire nasal cavity was lined with a layer of tenacious mucus, which I removed by means of a spray of alkaline water, and found that the turgescence of the mucous membrane had diminished so much that the patency of the canals was normal. There was not the slightest tenderness over the forehead, and all the sense of constriction had passed away.

Since this time Mr. P— has had repeated manifestations of coryza, with the usual accompaniment of frontal headache, but this always disappears as soon as he has made several inhalations of the fluid.

Chronic catarrhal rhinitis, when accompanied with hypertrophy of the mucous membrane, is also often attended with more or less pain in the frontal region.

¹ Muller's Archiv für Anat. Physiologie, etc., p. 147, 1853.

¹ Die Anatomie des menschlichen Kopfes, p. 359. Tübingen, 1867.

When we consider the fact that the frontal sinus and the nasal cavity are in such direct communication, we can hardly be surprised that disease of one cavity is frequently attended with a similar condition of the other. According to Zuckerkandl¹ there is one opening leading into the ostium frontale in the anterior portion of the infundibulum, and another between the insertion of the anterior extremity of the middle turbinated bone and the processus uncinatus, or one of the anterior ethmoidal cells.

This predisposes to consecutive inflammations of the frontal cavities, and, in fact, they are more frequently affected than any other of the pneumatic adnexæ, excepting the antrum of Highmore. The favorable position of these cavities, and the form of the foramen renders a restoration to a healthy condition more probable than in the other pneumatic spaces, as the fluids and secretions contained in them can readily be drained off. In a healthy condition, the mucous membrane lining this sinus does not secrete, but when it is diseased its discharges are similar to, but less in quantity than, those thrown off by the pituitary membrane. As the infundibulum may be occluded either by a swelling of its lining membrane or by pressure from a thickened turbinated bone, the secretion must increase in bulk until it either finds a natural outlet or forces its way through the roof of the sinus into the dura mater. Fortunately this latter is but a *dernier ressort*, which is but rarely encountered. I have known several cases of severe, persistent headaches, which have had all the changes of treatment rung upon them, and have only disappeared when the nasal cavity was restored to its normal condition.

Mrs. C. R—, aged twenty-four years, recently married, has, since her fourteenth year, suffered from continuous distressing headaches, which have been most intense in the frontal region. She informed me that during these ten years she cannot recall a single day during which she was free from pain. On close questioning I found that her paroxysms were always increased during wet weather; but she could not recall the fact that the season of the year exerted any special influence on her affection.

At one time or another Mrs. R— has been under the care of almost every authority in New York, in hopes of finding relief; but, in spite of the most varied forms of treatment, she has derived no lasting benefit. For some time past, however, she has noticed a considerable obstruction in both nasal fossæ, which interfered with respiration, and for the relief of this condition she came to me.

On examining the nasal cavities I found a diffuse thickening of the entire pituitary membrane, with decided hypertrophy of the anterior extremities of both the inferior and middle turbinated bones. The bulk of the former was so much increased that it completely closed the inferior meatus, and its inner surface was in immediate contact with the septum narium. Posterior rhinoscopy showed but slight thickening of the posterior ends of the bones; but I found the entire surface covered by a thin layer of muco-pus.

On applying pressure over the frontal sinuses the patient complained of some pain, but stated that she often did the same, as it seemed to afford some relief for her headache.

As a result of my examination I advised a removal of the hypertrophied tissue of the turbinated bones, hoping in this manner to relieve the nasal obstruction. The patient absolutely refused to consent to any operative measures whatever, but begged me to apply any other form of treatment which might afford her some relief. I thereupon cleansed the nasal cavity thoroughly by means of a coarse spray of Dobell's solution, and gave the patient a quantity of Hegar's fluid, in the hope that by irritating the mucous membrane and gustatory nerves I

might stimulate an active secretion. Two days later the patient returned, stating that the cleansing of the cavity had somewhat relieved the nasal obstruction, but the headache had not diminished. I again douched her thoroughly, and after a careful cleansing of the cavity, I insufflated a quantity of German sternutatory powder, called Schneeberger's sneezing powder, composed principally of finely powdered white hellebore (which can be procured at any German pharmacy), into the middle meatus, on both sides. I endeavored to drive the powder as nearly as possible to the orifice of the infundibulum. The patient soon began to sneeze violently, and continued to do so between forty and fifty times. This sneezing was not attended with any pain, and was soon followed by a profuse discharge of mucus from the nose.

Before leaving me the patient expressed herself as already much relieved. During her absence the discharges increased in quantity, and when I again saw her, after an interval of three days, I observed a very decided diminution of the thickening of the pituitary membrane. On the evening after the last treatment the headache had been greatly relieved, and for the two days following the pain was much less. I repeated the above applications six or seven times, at intervals of three days, with increasing benefit to the nasal stenosis and headache, and then gave the patient a quantity of the powder and a Davidson syringe, for nasal irrigation, with instructions to use both daily. I last saw her on January 26th, when she suspended further visits and treatment, owing to an imminent confinement. A few days ago, however, I learned that Mrs. R— had been entirely free from headache for nearly two months, and the nasal obstruction had almost disappeared.

We find that in this case an undoubted catarrh of the frontal sinuses was relieved, and, perhaps, cured simply by stimulating the mucous membrane to active secretion, thereby diminishing the congestion and consequent increase of bulk which caused an obstruction of the efferent passages. There are, however, many cases in which the mucous membrane and the turbinated bones are so hypertrophied that operative procedures alone will suffice to remove the obstruction.

Hartmann¹ has recently reported two cases of obstinate supraorbital neuralgia, due to empyema of the accessory cavities of the nose, in consequence of obstruction to a free discharge through the middle meatus.

Two years ago I had under treatment a case which strikingly illustrated this state of affairs. Mr. H. K—, aged twenty-seven, had suffered for many years from chronic conjunctivitis with nasal catarrh. He had been subject to many attacks of coryza, and in the winter of 1880–1881 contracted a violent cold, which was complicated with intense pain in the forehead, which remained even after the disappearance of the original trouble. The pain was so continuous, and the photophobia so intense, that he was compelled to absent himself from his business, and after the lapse of several weeks he consulted me for the relief of the nasal obstruction.

On examining the nose I found the mucous membrane hyperæmic and slightly swollen throughout. The nasal septum was deviated below to the right side, and above to the left, thus diminishing the size of both the middle and inferior meatus. The turbinated bones were greatly hypertrophied on both sides, so that but little air could enter on either side. There was a total absence of the sense of smell, and the voice was characteristic of an obstruction of the passages. In attempting to gain a better view of the cavities, I pushed the turbinated bones aside, and found them covered with a thick layer of creamy pus. Posterior rhinoscopy merely showed a swelling of the mucous membrane on both sides of the septum.

Pressure on the supraorbital notches caused intense neuralgic pain, which extended over the entire frontal region, but was not comparable to the paroxysms which set in every afternoon and lasted throughout the greater

¹ Normale und pathologische Anatomie der Nasenhöhle, etc. Wien, 1882.

¹ Berlin. klin. Wochenschrift, No. 48, 1882.

part of the night. At these times there was generally a profuse discharge of fetid pus from both nasal fossæ.

I had but little doubt that the pain was due to the nasal affection, and to satisfy myself on this point I inflated the nasal cavity by means of Politzer's method, as suggested by Hartmann.¹ After this I cleansed the passages thoroughly with an alkaline solution. This done, the patient felt himself much relieved, the pain and the fullness of the head being greatly lessened.

In order to enable the pent-up secretions to discharge freely, and to restore the nasal fossæ to their normal potency, I removed the hypertrophied tissues of the turbinated bones by means of the galvano-caustic snare. This was done in three sittings, and was followed by a marked improvement in the condition of the patient, although there was some pain in the supraorbital region for a few days after the last operation.

Before I undertook the treatment of the case, the patient had been under the care of one of the most eminent physicians in this city, who employed every remedy at his command for the relief of the neuralgia, but without avail. As soon as I cleansed the nasal cavity and allowed some of the pent-up secretions to escape, a decided improvement was noticeable, and when the connection between the nasal and frontal cavities was restored all trouble disappeared. I do not think that there can be any doubt but that the neuralgia and the obstructed condition of the nasal fossæ stood in the relation of effect and cause.

For nearly two years the patient has been able to breathe freely through the nose, and since that time, without any further treatment, the chronic affection of the conjunctiva has disappeared spontaneously.

I am somewhat at a loss to explain the manner in which the neuralgia was superinduced, whether it was due to a direct pressure upon the trunk of the supra-orbital nerve or caused by a reflected irritation of some of the many branches of the trigeminal nerve. Hack² has reported a number of cases of nasal affections combined with reflex neuroses, and found that the latter invariably disappeared as soon as the cause was removed or the irritability of the diseased surface was diminished.

Affections of the deeper parts of the nasal cavity and the ethmoid and sphenoidal sinuses may give rise to such grave conditions that disease of the brain or its meninges may be suspected. Schwalbe, Axel, Key, and Retzius³ have demonstrated the fact that not only can the lymphatics of the nasal mucous membrane be injected from the subdural and subarachnoidal spaces, but if force be used the fluid will pass through the lymphatic canals to the surface of the nasal mucous membrane. We thus see that there must be a direct communication between the nasal and the cerebro-spinal cavities. It is therefore fair to conclude that if these channels are obstructed there may ensue an increased pressure on the cerebro-spinal fluid. It occurs to me here, that the cases of exudation of fluids from the nose, reported a few years ago by Sir James Paget and Dr. Althaus, may be attributed to an unusual patency of these communicating canals, which favored an egress of the cerebro-spinal fluid.

In December, 1882, Mr. Henry B—, of Chicago, came to me to learn whether or no he had any nasal polypi. The patient had for several years been suffering from continuous headaches, referable to the base of the brain and the occiput, was greatly emaciated, suffered from insomnia and loss of appetite, and from difficulty of respiration. During the greater part of the time he had been under the care of Dr. Jewell, of Chicago, who, however, finding that he could not afford him any relief, and suspecting the true cause of the trouble, advised Mr. B— to consult a specialist for diseases of the nose and throat. My patient did apply to several physicians, who failed to give him any satisfactory information, and he,

therefore, determined to come to New York. On examination, I found that the posterior nasal space, on both sides, was absolutely filled with polypoid growths, which I determined to remove. Owing to the prostrated condition of the patient I was compelled to proceed very slowly, but in the course of several weeks I removed a sufficient number of polypi to completely fill an ounce vial. I operated at first with a Wilde's snare, and later by means of the galvano-caustic loop, hoping thereby to serve the double purpose of removing the growths and destroying their attachments.

The patient began to improve perceptibly after the removal of the most prominent polypi, which enabled him to breathe somewhat through the nose. As the patency of this passage was restored his headaches disappeared, his appetite returned, he was able to sleep without the aid of narcotics, and, in short, when he left me for the South, about five weeks ago, he was, to all intents and purposes, a well man.

Zuckerkandl¹ says, "that polypi arise in the majority of cases from ethmoidal turbinated bones and the tissues of the middle meatus. They are frequently found near the orifices of the ethmoidal foramina, and thereby contribute, by their gradual growth, to an obstruction and inflammatory condition of the cellular cavities contained in the ethmoid and sphenoid bones." This condition must naturally have an influence in causing more or less marked congestion of the base of the brain, producing headaches which may be irremediable, owing to the great difficulty of arriving at a satisfactory explanation of the cause of trouble. It is almost impossible to effect a radical cure, owing to the inaccessibility of the polypoid growths, as they are generally situated in a part of the nasal cavity which cannot well be reached by any surgical apparatus.

Of all the cavities which are connected with the nose, the antrum of Highmore is most liable to disease, owing not only to its intimate relations with the nasal fossa, but to irritation and inflammation caused by the development of the teeth. Diseases affecting the nasal cavity are readily propagated to the cavity of the maxilla, but owing to the peculiar situation of the communicating canal are not so easily relieved. It will be remembered that the foramen is situated in the upper portion of the inner wall of the antrum, and that it connects with the nasal fossa just below the middle turbinated bone. While in a healthy condition the lining membrane of the antrum does not secrete more fluid than can be absorbed by the lymphatics. But in disease these secretions are increased, the absorbents cannot carry them off, and they will accumulate until they reach almost the roof of the cavity, when they may force their way through the foramen into the nose. In the meantime, however, the patient may suffer from great pain in and about the upper jaw, owing not only to the inflammatory process but from the weight of the column of fluid contained in the cavity. This pressure and the propagation of the diseased condition to the teeth give rise to neuralgias, and even the teeth may become seriously affected.

In many cases it becomes necessary to perforate the antrum in order to procure a discharge of its contents and to allow the application of topical remedies. The most common mode of procedure, and the one which I have repeatedly employed, is to extract the second upper molar tooth on the affected side, and then to perforate the alveolus so that a direct communication between the cavity and the external air is established. Zuckerkandl,² however, suggests that it is more feasible to perforate the outer wall of the nasal cavity just behind and below the infundibulum, where the sinus is only separated from the nasal fossa by soft parts.

Mr. J. P—, of Newark, was frequently subjected to acute attacks of nasal catarrh, which were generally attended with more or less tenderness of the right upper jaw, and shooting pains into the corresponding eye and

³ Hack; loc. cit.

¹ Op. cit., p. 79.

² Op. cit., p. 143.

ear. At these times he was always affected with toothache, which led him to consult his dentist, who gave him the assurance that his teeth were perfectly sound. In November, 1882, Mr. P—— was again affected with a severe cold, which, however, disappeared after the lapse of a few weeks. The pain in the upper jaw remained, however, and the patient observed, from time to time, a faint fetid odor in his nose, and whenever he lay on the left side he could distinctly taste some putrid fluid. Fearing that he might be affected with nasal catarrh he came to me for advice.

On examination I found a general hyperæmia of the nasal mucous membrane, with some hypertrophy of the inferior turbinated bones, especially so on the right side. There was a thin deposit of creamy pus in the middle and inferior meatus which emitted a very offensive odor. The right cheek was rather puffy, and pressure over the antrum gave rise to considerable pain, which was most marked near the infra-orbital notch, the place of exit of the superior maxillary branch of the trifacial nerve.

After thoroughly cleansing the nasal cavity I bade Mr. P—— to bend his head strongly toward the left side, and dilating the nares and illuminating the cavity I could see the pus exuding from the orifice of the maxillary foramen. I now felt certain that I had to deal with a chronic purulent catarrh of the antrum of Highmore, and determining to attack the disease boldly, I took the patient to a dentist, who unwillingly extracted an apparently healthy second upper molar tooth. On the next day I perforated the alveolus with a small trocar, and was pleased to have this followed by a copious flow of bloody pus through the canula. The quantity of fluid evacuated was more than three drachms. I now introduced a small drainage-tube, such as is used in trepanation of the mastoid cavity, and injected a one per cent. solution of carbolic acid into the cavity. After an interval of a few minutes I allowed this fluid to drain off, and ordered the patient to return on the following day. I then injected a fluid drachm of a two and one-half per cent. solution of chloride of zinc, which I retained in the cavity a few minutes by letting the patient lie down and turn his head toward the left side. When he again resumed the erect posture this solution escaped through the drainage-tube. I made fifteen injections, at intervals of from three days to a week. At this time the tenderness had disappeared, and I discharged the patient with instructions to return within a month. During all this time the drainage-tube remained *in situ*, and when Mr. P—— returned he informed me that at first he noticed an occasional exudation of fluid from the opening, but none had escaped for nearly three weeks. On examination I found no evidence of disease, and therefore removed the canula, intending to allow the fistula to close up. More than two months have now elapsed, and, in spite of several attacks of acute coryza, Mr. P—— has had no further trouble in the antrum.

I might continue to multiply instances indefinitely of the causal relations between diseases of the nasal and accessory cavities. But I hope that I have succeeded in calling attention to the necessity of making a careful examination of these parts in all cases where symptoms of headache, neuralgia, and other pains exist, which cannot be traced to other sources by the usual methods of examination.

DEAD DRUNK.—"Dead drunk" is described by savants of the Paris Biological Society to be a condition in which there is a proportion of one part of alcohol to one hundred and ninety-five parts of blood in the circulation. Should the proportion ever come to be one part of alcohol to one hundred of blood, death would ensue. This might happen, and in fact has happened repeatedly, where a very large quantity of alcoholic liquor is swallowed at one time and quickly. In ordinary drinking consciousness is lost, and with it the power to drink more, before the proportion of alcohol in the circulation becomes fatal.—*Medical and Surgical Reporter.*

THE HOT-WATER RETROJECTION IN THE TREATMENT OF GONORRHOEA.

By H. HOLBROOK CURTIS, M.D.,

NEW YORK.

DURING the past twenty years in no disease has there been less advance made therapeutically than in the treatment of simple gonorrhœa. Of late there have appeared in the London *Lancet* many articles upon this subject, but no especial claim has been advanced for any method that will effectually abridge the orthodox three weeks' limitation of this troublesome difficulty. I propose, without entering upon the discussion as to the probable bacterian origin of the malady, to explain a course of treatment that I have employed for two years with very excellent results.

Endoscopic examination reveals that a current of hot water passed continuously through the urethra primarily congests and secondarily renders anæmic the mucous membrane, in the same way that a hot bath affects the fingers. It is observed also that the urethra, after being acted on for some time, will endure water of a temperature that cannot be tolerated by the hand. Taking advantage of this fact, I have arranged an apparatus by means of which one is enabled to pass several quarts of hot water through the urethral canal from the prostatic portion outward, increasing all the time the temperature of the water until the thermometer oftentimes indicates 180° to 190° F. I have repeatedly passed ten quarts of water from behind forward in this manner, continuing the retrojection for some time after the point of toleration has been reached. This varies much in different persons. It remains then to pass a mild astringent solution through the same catheter that has been employed for the retrojection. Preferably I use a suspension of iodoform in a glycero-tannin solution in the following proportions:

R. Acidi tannici,	
Iodoformi.....	āā ʒij.
Glycerinæ	ʒj.
Aquæ	ʒiij.

Sig.—Heat, shake, and inject.

After the injection the catheter is withdrawn and the patient is directed to return in twelve or twenty-four hours, as the case may warrant.

As I intend shortly to publish the histories of some twenty cases of gonorrhœa and gleet that have been treated in this way, I will here but briefly outline the method and results.

In twelve cases of undoubted acute gonorrhœa the discharge has been entirely checked in three days. In two cases I have succeeded in aborting the disease by one prolonged (ten quarts) thermo-retrojection. In six cases the disease lasted six to ten days, while a case of chronic gleet that had made the round of the profession for nine months succumbed in seven days to dilatation and retrojection.

It has been noticed that cases that have been treated for some time with strong mineral injections do not respond nearly as quickly to the hot-water method. I have yet to see, however, a "fresh case" of gonorrhœa, in which no previous injection has been employed that will not recover within a fortnight if the retrojection is properly administered.

From a careful study of more than forty cases I claim for hot retrojection:

First.—The course of the disease is shortened by, at least, two-thirds, making the average limit of the case—viz., stoppage of the discharge—nearer one week than three.

Second.—The discharge immediately changes from a purulent to that of the nature of gleet, and is reduced to a very small quantity.

Third.—There is absence of chordee and pain in passing urine.

Fourth.—Stricture as a sequel is improbable.

Fifth.—The usual inconveniences of the disease are done away with.

A brief description of the apparatus employed is as follows: An ordinary wooden armchair is half-mooned in the front of the seat to admit a tall cuspidor. A pulley is rigged on the ceiling by means of which a tin pail with a lamp beneath is elevated. A rubber tube, provided with a stopcock and connection, leads from the pail and at any time may be fitted to an ordinary No. 8 English flexible catheter. The necessity of having a catheter with a bulbous end to prevent water passing into the bladder is purely imaginary. I would also state that an ordinary Davidson's syringe may be used, the patient giving himself the retrojection from the pail on a chair beside him; this is not as convenient, however, as the gravity apparatus. When the water is of the proper temperature, say 120° F., the catheter is vaselined and introduced to within an inch of the prostate, connected with the rubber tubing and the pail elevated to such a height that the flow is brisk. The lamp under the pail will keep the temperature of the water slowly increasing. The patient holds the catheter in position and may read the morning paper until the water becomes uncomfortably hot. The lamp is then extinguished and the retrojection proceeds at the point of toleration. After this has gone on for a sufficient time, a syringe of the *injection* formulated above is thrown in and the catheter withdrawn. If the patient is unable to come back at once give him the same prescription for urethral injection or slightly modified to suit the particular case, with directions to use it twice a day, until he can return. As an adjunct to this the only internal treatment I employ is bicarbonate of soda in five-grain compressed tablets, to take ten daily. Heretofore my cases have been confined to private practice, but recently, at the kind invitation of Professor Sturgis, I had an opportunity to demonstrate this method at the Charity Hospital, where I am told the results have been so gratifying that Dr. Sturgis has promised to compile the statistics in regard to this mode of procedure, which seems so rational that it will undoubtedly supersede the ordinary injection treatment.

Several writers have advocated warm water "irrigation" of the urethra in gonorrhoea and have claimed more or less success for their methods, but no one, to my knowledge, has shown any statistics that can compare with those obtained by prolonged progressothermal retrojection. More than a brief outline of the subject would be too lengthy for an article of this kind, but there is such a field for experiment afforded in this direction, I take this opportunity of placing some fragmentary data before the profession.

A SINGLE CASE OF OVARIOTOMY AND WHAT MAY COME OF SIMPLE CLEANLINESS.¹

By DAVID LITTLE, M.D.,

ROCHESTER, N. Y.

THREE years ago this Society was entertained and instructed by Dr. J. Marion Sims in a graphic portrayal of Thomas Keith and his ovariectomies. It must dwell fresh in the memory of each one who heard the recital. Quoting a single paragraph will suffice as a text for what I have to offer:

Said Sims: "If Keith cured from 86 to 90 per cent. before antiseptics, while others were curing 70 or even 80, and if he now cures 97 per cent. with it, while others cannot get even 88 or 90 with it, then I thought there must be something besides antiseptics to account for this difference. With this feeling I went to Edinburgh, and I think I have learned the secret of his great success."

This secret (if I heard rightly and remember correctly) might be summarized in the one word—*cleanliness*. Cleanliness that is next to godliness; cleanliness that is godliness; for to do good is to be godly, and as a bene-

factor in surgical operations cleanliness stands pre-eminent.

Almost three years later came the wonderful record of Lawson Tait—one hundred consecutive ovariectomies with but three deaths! and one of these due to "immediate suffocation," so as in no wise to be attributable to septic poison. "*and in no case was any detail of Listerism used.*"

In homely phrase, "put this and that together," and is it not apparent that Listerism played but an insignificant part in the success of Keith reported to us in 1880?

So Keith and Tait can "cry quits." Ninety-seven per cent. of recoveries tallied to each! One with his germicides and germ-shields, and the other germ defying; but both doubtless worshipping at the shrine of cleanliness.

Without further preface, let me introduce my single case of ovariectomy, nor let those with "their flocks and herds" who count their operations by the hundreds, smile at my lone "ewe lamb." Bear in mind the Scotch proverb, "Every mickle makes a muckle." Every little unit helps to swell the sum of experience.

Regina E.—(resident of Wheatland, Monroe Co., N. Y., of German nativity, aged forty-six, married and the mother of three children) first noticed a lump in her left side (iliac region) about June 1, 1881, which grew rapidly, invaliding her, so that with her illness and poverty she was forced to become an inmate of the County Almshouse, on February 28, 1882. Dr. Backus, the attending physician, made a diagnosis of ovarian tumor, and asked me to see her, in the latter part of March following.

We found a fluctuating tumor occupying the abdominal cavity and extending from pubes to near the ensiform cartilage, and lying largely to the right of the median line. It was slightly movable, and we thought we could trace its attachment and pedicle down into the right iliac fossa, though the woman insisted that the growth began in her left side.

Examination per vaginam showed the uterus to be tilted with its fundus to the right side.

The patient was bedridden and in constant pain, for which she had for months been taking hourly doses of morphia.

The operation was done on April 22d, in a room 25 x 18 x 11 feet in dimensions, thus having an air capacity of 4,950 cubic feet. This room was in the southeast corner of the third story, and was furnished with five windows and a door with a transom.

It had been thoroughly cleansed, painted, and white-washed a few days before. As soon as the woman, incased in flannel, was covered in bed, each of the five windows was opened, top and bottom, and so left as long as the patient occupied the room. The transom and door were kept closed, because of the existence of ten suspicious cases of post-partum fever lying in a room across the hall.

The instruments used (Thomas' case) were new. Sponges new and acid-cleansed. Anæsthetic, Squibbs' sulphuric ether.

Present and assisting, Drs. Backus and Montgomery of Rochester, Dr. Richmond of Livonia, Dr. Roseboom of Utica, and Messrs. Moore and Fulton, internes.

With hands prepared only by soap and water with a nail-brush, we were ready to begin. Temperature of room about 90° Fahrenheit.

The cut in the abdomen was four inches long. Before opening the peritoneum, all oozing of blood was stopped. Adhesions were found to abdominal wall and to omentum. Pedicle of tumor was traced to left side; tumor a monocyst; pedicle was twisted (which perhaps explained her pain). After emptying and drawing out the sack, the pedicle was tied in two halves by a strong, double silken ligature.

The pedicle was severed three-fourths of an inch above this, and its raw end smeared with liquid persulphate of iron. Two fine silken ligatures only were needed to se-

¹ Read before the State Medical Society, Albany, N. Y., February 6, 1883.

cure bleeding vessels. All these intraperitoneal ligatures were cut short and left *in situ*.

Sponges were freely used in the bottom of pelvic cavity, until they came forth clean and stainless as they entered. Then the cut was closed with interrupted sutures of silk. Operation was completed and the patient in bed in three-quarters of an hour.

And now I have to confess that (unlike Tait's cases) in this one were used two details of Listerism, so incomplete, however, that they should be admitted as inconsequential. For Lister and his imitators insist that, with a missing link in its details, the whole system falls to the ground, and fails in effecting its object of excluding the noxious germs.

For form sake, and to appease the fears of assisting surgeons, the water used was carbolyzed, but only to the extent of a drachm to the pint, *i. e.*, less than one part to one hundred and twenty! What part this inundated carbolic played in the destruction of disease-germs, if such there be, I know not, my care being that the vaunted germicide should not in this (as in many authenticated cases) prove to be a homicide.

Again, after the wound was closed, a piece of lint soaked in the thymol (1 part to 1,000) was laid on it, and over this was pinned the customary flannel binder. "Only this and nothing more." I should have mentioned, while describing the operation, that no one was asked to thrust a hand into the opened abdomen for any purpose. The gentlemen were polite enough to take my word for it that bladder, uterus, and remaining ovary were healthy, and the last sponges coming spotless from the pelvic floor satisfied them that we had, at least, made *clean* work of it.

The size of the tumor had to be estimated, owing to an accident. When the trocar was withdrawn, the rubber tubing attached to the canula was forced off, and most of the fluid escaped onto the floor; fortunately, none of it leaked into the peritoneal cavity. It was judged that about three gallons flowed from the cyst. The liquid was of a dark straw-color, and was albuminous.

And now as to results. The poor woman with her tumor lost her pain, lost her appetite for opium, and, in due time, lost her worn and haggard look and regained complete health. Only three-fourths of a grain of morphia in all was given to her after the operation. Her pulse never exceeded 116 per minute, and her temperature reached its highest point at $100\frac{2}{3}^{\circ}$! Both dropped to normal standard on the third day, and thereafter so remained.

On June 20th the woman walked away from the almshouse to the house of a friend a mile and a half distant. She called at my office last August and expressed herself as "perfectly well and able to do as hard a day's washing as any Dutch woman going."

In giving this history, for brevity's sake I have refrained from entering into the many little details which are known to be so essential to the proper performance of the operation. Suffice it to say I kept steadily in mind the lesson learned from Dr. Sims—Cleanliness, cleanliness, above all things cleanliness. To the surgeon's motto "*tuto, cito, jucunde*," might well be added "*et munditer*."

To this scrupulous cleanliness before, during, and after the operation, together with the free admission of air and sunlight throughout the management of the case, in my opinion, belongs the credit of its successful issue.

You remember what dear, soft-hearted old Uncle Toby said, as he bore unhurt the troublesome fly (which he vainly fought, but finally caught) to the open casement: "Go! Surely the world is wide enough for both thee and me." So said we to the bacteria, only (because we had been told they vastly outnumber the fly) they were given vent through five windows instead of one.

Vaccine virus needs but the slightest abrasion to effect its entrance into the system; if the unrecognized, or at any rate unconvicted micro-organisms are so numerous,

omnipresent, and dangerous, why don't they enter on their errand of destruction through like small gateways? "Ay, ay, a scratch, a scratch; marry 'tis enough. . . . No, 'tis not so deep as a well, nor so wide as a church door, but 'tis enough, 't will serve." And why do not the daily accidents of prick or scratch make us constant victims of septicaemia?

Common experience teaches that such trivial wounds are best left alone exposed to the air, and only covered, in nature's own time and way, with her plaster of dried blood and lymph. This common experience is but the outcome of an instinct. The dog licks his wound, the child sucks his; so the wound is cleansed.

Years ago, a certain "quack," wiser than his day and generation, or it may be building better than he knew, proclaimed to the wounded knight that he could heal his hurt by anointing the offending weapon, if only the sick knight would meanwhile keep his wound clean. His marvellous success soon banished salves and plasters, and there ensued open air and water-dressings. But now, again, the fear of the ultra-microscopic fiend brings back plaster and salve and in turn banishes air and water as being probable vehicles of the infinitesimal vermin.

Pasteur and his co-workers are engaged in investigations of absorbing interest, from which may some day come an "output" that shall give us an applied science, working a revolution in the healing art. Meanwhile, let us "hasten slowly," and hesitate to fight an unseen and perhaps imaginary enemy with uncertain and dangerous weapons; weapons that, like the boomerang, may be more destructive to friend than foe.

A CASE OF IDIOPATHIC (?) PURULENT INFLAMMATION OF THE SEROUS MEMBRANES OF ALL THE GREAT CAVITIES.

By FRANCIS P. KINNICUTT, M.D.,

PHYSICIAN TO ST. LUKE'S HOSPITAL, THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL, ETC.

C. F.—, male, aged twenty, grocer by occupation, was admitted into my wards in St. Luke's Hospital, February 4th.

The patient's condition was such that a reliable history could not be obtained from him. Doctor Robert Campbell, former house physician of the hospital, under whose care the patient had been, and by whom he was sent to the hospital, has kindly furnished me with the following facts. The patient had complained during the previous ten days of headache, wandering muscular pains, loss of appetite, and general malaise; had been free from chills, but was feverish. There had been several attacks of epistaxis during the same period. His bowels had been regularly moved; there had been no cough or sore throat, nor any discoverable eruption. The patient was first seen by Dr. Campbell on February 2d, and an examination at this time of the throat and chest revealed nothing abnormal. There was no eruption; there was general sensitiveness over the abdomen. Temperature, 103° ; pulse, 120; respiration, 24.

On the following day he was found lying in bed covered only with a horse blanket, in a room without a fire, and which was very cold.

The patient complained of stabbing pains in left side. Examination revealed pleuritic crackling over the whole of left chest, posteriorly. On the succeeding day the patient was admitted to the hospital. On admission he was well nourished, tongue dry, face congested; respiration, 40; pulse, 138; temperature, $104\frac{1}{2}^{\circ}$ (mouth); complains chiefly of pain in left side. P.M.—Patient slightly delirious; respiration, 50; pulse, 140; temperature, $105\frac{1}{2}^{\circ}$. Severe attack of epistaxis.

Physical examination of the chest was necessarily imperfect on account of patient's condition. There was marked flatness on percussion over the lower three-fourths of left chest, posteriorly, with distant respiratory

sounds and exaggerated voice over the same area; examination of the urine showed the presence of a small amount of albumen.

February 5th.—Respiration, 58; pulse, 152; temperature, 105 $\frac{1}{2}$ °. Flatness over whole of left chest, anteriorly and posteriorly, with distant respiratory sounds. Heart-sounds hardly distinguishable; impulse absent. Area of cardiac dullness cannot be defined on account of general flatness over left chest. Pericardial effusion believed to be present in addition to pleural. Exploratory puncture into left pleural cavity revealed the presence of a sero-purulent effusion. Aspiration performed and sixteen ounces of thin creamy pus, free from odor, withdrawn. Immediately previous to aspiration, respiration, 50; pulse, 132; temperature, 105°. Two hours later, respiration, 36; pulse, 138; temperature, 102°.

February 6th.—Patient passed a comfortable night; respiration, 44; pulse, 152; temperature, 102.5°. Flatness over whole of left chest, anteriorly and posteriorly. Aspiration again performed and sixteen ounces of sero-pus withdrawn, but with only very temporary improvement in patient's condition. The fluid in the pleural cavity apparently accumulated almost as rapidly as it was withdrawn; the physical signs remained unchanged; the symptoms of cardiac failure gradually became more marked, and death occurred on the 9th.

Autopsy, fourteen hours after death, by Dr. Ferguson, pathologist to the hospital.—Body well nourished; rigor mortis well marked; no cedema; no cutaneous lesion. Peritoneum: Visceral and parietal peritoneum congested, especially in pelvic cavity and over coils which dip into it; small amount of pus and lymph in this situation. Thorax: Right pleural cavity contains twenty-two ounces of sero-fibrinous fluid; left pleural cavity, seventy-four ounces of sero-pus. The right lung is markedly congested and cedematous; bronchi congested; left lung compressed against spinal column, seems totally deprived of air; and is covered by recent lymph. Heart: The pericardium contains about six ounces of fluid, consisting of serum, pus, and fibrin; valves normal; muscular tissue of heart normal in appearance, surface covered with recent lymph. Spleen slightly increased in size, normal in appearance. Kidneys normal in appearance. Stomach, intestines, bladder, urethra normal. Liver apparently contains a slight excess of fat. Larynx and trachea normal. Joints examined and found to be normal. Examination of the brain not permitted.

Microscopic examination of the different tissues showed only a slight degree of fatty degeneration of the cardiac muscle and swelling, with a cloudy appearance of the epithelial lining of the renal tubules.

Remarks.—So general an inflammation of a purulent character of the serous membranes of the great cavities is, in itself, an interesting observation. Such inflammations are of occasional occurrence in simple pyæmia and in the metastatic form. They are more rarely seen accompanying the acute infective diseases and as secondary to Bright's disease. Pericarditis, with bilateral pleurisy, is of sufficiently common occurrence in acute inflammatory rheumatism, but the exudation is usually of a sero-fibrinous character. In the present case, a very careful investigation of the immediate previous history of the patient failed to reveal the existence of any of the usual causes of pyæmia, the presence of an acute infective disease, of a renal affection, and finally, of any of the symptoms of rheumatism.

A very complete post mortem examination corroborated the clinical evidence of the absence of any possible source of pyæmic or septic infection; the kidneys, moreover (with the exception of presenting the cloudy appearance of the epithelium of the tubules not unusual in individuals dying of acute disease) were wholly free from disease. The inflammation of the peritoneum was almost wholly confined to that portion lying within the pelvis, indicating the absence of the influence of contiguity of structure in its production.

The very acute nature of the morbid process (the illness only extending over a period of ten days), its occurrence in an individual of exceptionally fine physique, the entire absence of any of the usually recognized causes of similar wide-spread serous membrane inflammations are noteworthy. I hesitate to pronounce the pathological process idiopathic in character, yet all the evidence obtainable in the case would seem to justify such an opinion.

CASE OF CYANOSIS DUE TO CONGENITAL CLOSURE OF AORTIC ORIFICE.

CHILD LIVING TWENTY-SEVEN DAYS.

By ALFRED MEYER, M.D.,

NEW YORK.

THOUGH cases of congenital malformation of the heart have not infrequently been put on record, with few exceptions these have been cases of malformation of the right side, with possible secondary changes in the left. Moreton Stillé, writing in 1844 (*American Journal of the Medical Sciences*), mentions sixteen forms of congenital heart disease giving rise to cyanosis, but does not even allude to atresia or stenosis aortæ. J. Lewis Smith ("Trans. N. Y. Ac. of Med., 1863," p. 335) publishes one hundred and ninety-five cases of cyanosis, of which seven were cases of disease of left side of heart, and of these seven only one of complete closure of the aortic orifice (Case 143). Rauchfuss (Gerhardt's "Handbuch d. Kinderkr.," vol. iv., pt. 1, p. 123) has collected twenty-four cases of congenital disease of the aortic orifice, in six of which there was stenosis and in the remaining eighteen atresia.

Of one hundred and thirty-nine cases of congenital heart disease which I have collected from the journals of the last fifteen years, there is not a single case which bears the remotest resemblance to my own, nor have I been able, after diligent search, to find a heart like mine in any of the pathological collections of the city. Of course, when speaking of the rarity of occlusion of the aortic orifice, I exclude cases of stenosis and of atresia aortæ at or near the points of insertion of the ductus arteriosus. Of these latter numerous instances are on record. Thus Eppinger (*Prager Viertelj.*, vol. cxii., p. 31), in a historical review of the subject, collected forty-two cases of this kind up to the year 1871, to which he added two more cases of his own; whilst Kriegk (*Prager Vier.*, vol. cxxxvii., 1878) collected and tabulated fifty-six cases, beginning with one observed by Paris at the end of the last century, and described in "Desault's Journal,"¹ which is probably the first case on record. To this series of cases I am able to add nine² more, omitted by Kriegk or published since the appearance of his article. A great many of this kind of cases live many years without any appreciable disturbance of health. Living to fifty and sixty years of age is not at all uncommon, and Reynaud (quoted by Kriegk) reports the case of a man dying at ninety-two years, in whom this malformation was found.

My own case is not one of this more common and favorable kind, but of the rare and fatal variety of *complete absence of the aortic orifice*. It has already been reported by me at the Society of German Physicians, but will surely prove of interest to a wider circle—a justification for its publication in detail in this journal.

On the evening of June 7th last I was called in haste to see the patient in question, a male infant, twenty-four days old, whom I found in great dyspnoea, with marked cyanosis of entire body, and no radial pulse to be felt on either side. Curiously enough the pulsations in each

dorsalis pedis artery were full and distinct enough to permit of their being readily counted. At that time they numbered one hundred and thirty-five. On examination of the chest, to which, naturally, attention was first directed, nothing abnormal could be discovered in the lungs, but there was a distinct, loud, blowing systolic

murmur to be heard in the neighborhood of the second and third ribs to the right of sternum. The mother of the boy reported that he had been short of breath from birth, but that no discoloration of the skin was observable until some time in the third week, and that then the midwife pronounced the child to be suffering from "severe jaundice." The gradual increase of the dyspnoea at nursing, as well as the deepening cyanosis, finally impelled the

mother to seek other advice. This was on June 7th, when I found the condition as described above. The child was found dead in bed, somewhat more than forty-eight hours later. After a great deal of opposition, I was finally permitted to remove the heart through a small incision. The pericardium contained about three-fourths

of a drachm of clear serum. Heart-substance of a dark-blue color. Right auricle and ventricle both greatly dilated; foramen ovale pervious, pulmonary artery fully twice the normal size; ductus arteriosus pervious; left auricle about one-third the size of right one; walls of left ventricle about one-half inch thick, its cavity just large enough to hold a small pea, muscoli pectinati being fused into a solid mass. Mere traces of chordæ tendinæ to be seen. *Aortic orifice completely closed; no trace of semilunar flaps.* Ductus arteriosus leads into arch of aorta, which is about one-eighth inch in diameter, but ends as a blind sac at the base of the heart. Septum ventriculorum complete.

The circulation in this case was carried on by the right ventricle and the two auricles, the systemic circulation being supplied from the pulmonary artery via the ductus arteriosus.

The absence of a radial pulse, at a time when pulsations were to be distinctly felt in the dorsal arteries of the foot, seems to me accounted for by the fact that the arch of the aorta is more nearly a direct continuation of the ductus arteriosus than the vessels going to the upper extremities, and that hence the blood-current mainly took this direction.

A rather unusual feature of this case was the length of time the child lived—twenty-seven days. The one most nearly resembling it which I have been able to find in print lived only two days. It is the case of a girl reported by Canton in the London Pathological Society's "Transactions," vol. ii., p. 38.¹ The case quoted by J. Lewis Smith (No. 143) in the article already referred to lived four days.

A close inspection of the heart indicated that the malformation was due to an endo- and myo-carditis.

The causes of foetal endocarditis, as of many other foetal diseases, are obscure. Anxiety or fright are frequently mentioned in this connection. In my own case there was a history of this kind. When in the seventh month of pregnancy the mother was frightened by the severe scalding of one of her children, and shortly after nursed her husband during a severe attack of pleurisy. Be this as it may, the exciting cause of the endocarditis must certainly have acted after the end of the second or the beginning of the third month of pregnancy, for this is the period of closure of the ventricular septum, and, as we have seen, the closure was complete in this heart.

In the Transactions of the German Medical Congress,² 1882, Von Hoffman records a case of congenital heart disease, in which the placenta was the seat of numerous recent and old extravasations. He advances the theory that pathological products had been introduced through villous absorption into the foetal circulation, and had thus given rise to endocarditis. He advises a careful examination of the placenta, and believes much light may be thrown on the etiology of congenital disease.

INFLUENCE OF FOWLER'S SOLUTION UPON THE HÆMOGLOBIN IN THE BLOOD.—From an investigation made to determine the effects of the medicinal administration of some remedies upon the proportion of hæmoglobin in the blood, Dr. Fenoglio, of Turin, concludes that the iron preparations vary considerably in their effects. Fowler's solution increases the hæmoglobin, and this becomes more marked the longer it is given. In spite of the general opinion to the contrary, the administration of Fowler's solution is indicated in anaemia, chlorosis, and in general in all conditions in which there is a decrease in the hæmoglobin, for the influence of this agent is very evident in increasing the proportion of the hæmoglobin. And, furthermore, its use increases the appetite and produces a general improvement in the bodily appearance and condition.

¹ Also included in Rauchfuss' series of cases.

² MEDICAL RECORD, December, 1882.

Reports of Hospitals.

THE TREATMENT OF FRACTURES IN BRITISH HOSPITALS.

(From our London Correspondent.)

THERE is, perhaps, no other province in the wide domain of Surgery, in which similar and equally satisfactory results are so commonly brought about by a variety of means than in the treatment of simple fractures of the limbs. And this is the case, not because any great diversity of opinion exists as to the end that is to be desired, for that cannot be alleged in this particular instance, but rather because the result sought for is in all cases identical, though capable of being accomplished by very many forms of treatment, which differ in this detail, and allow scope for the ingenuity and dexterity of the individual surgeon.

Fractures of the limbs are so common, that it is not a matter of surprise that we find at each institution some recognized method, which is sanctioned by custom and hallowed by time, for meeting all the more common forms of each injury, whilst any complication that may be found needs generally but a very slight modification of the apparatus. And this is rendered all the more necessary seeing that such injuries, except when complicated by some serious addition, such as severe injury to a joint or rupture of an artery, are treated in the first instance by the house surgeon, and the surgeon on his visit is rarely called upon to do more than approve, or at most to suggest some slight alteration in the apparatus.

Except there be some other injury, or on account of the feebleness of the patient, or in the event of some serious complication to a joint or artery, cases of fractures of the upper extremity are usually treated as out-patients, thus coming entirely under the care of the house surgeon and his dressers, and this renders it necessary that a convenient and portable apparatus shall be applied to keep the ends of the injured bone in good apposition. It would be impossible to enumerate the many ways in which fracture of the clavicle is dealt with, or the many ingenious appliances which have been invented by surgeons and by instrument makers; but speaking only of hospital practice, the result obtained by a simple bandage with or without a pad in the axilla, and applied so as to throw back the shoulder upon the injured side, to raise and keep steady the humerus, and to take off the weight of the arm, are as satisfactory as could be wished for. Sometimes a figure-of-eight bandage, with a sling for the arm, produces the desired effect, whilst in other cases where it is difficult to overcome the deformity, the surgeon must rely upon his skill in using and applying a bandage, with a pad secured in the axilla by a strap passing over the opposite shoulder.

Fractures of the scapula do not commonly occur without either severe bruising of the surrounding parts or some other more serious complication, of which fractured rib is by far the most frequent. When they do occur without any serious complication, the treatment consists only of a sling or bandage to steady the arm and take off the weight of the limb, and this is all that can be done if the acromion or coracoid process be broken.

Before speaking of the mode of treating the long bones in detail, it may be well to mention some of the materials which are in use in London at the present time for securing the position of fractures, after the application of splints has been dispensed with, as these means are not uncommonly found available in the first instance, and can be applied in many instances where there is no bruising, and where only one of two bones is broken, as happens particularly in the case of a fracture of the fibula or radius. The principal of these are, the starch or glue bandage, the plaster-of-Paris bandage, and one made stiff with dextrine, gum, and chalk, etc. A very useful material for this purpose has long been in use at St. George's

Hospital, and can be applied in the first instance in treating fracture of the fibula without bruising, and is almost invariably employed to put up fractures of the thigh or leg as soon as union has taken place and the splints can be laid aside. A piece of ordinary stout mill-board is cut to about the size necessary to embrace the limb; it is then soaked in hot water, which renders it pliant, and is shaped roughly to the limb, the edges being torn carefully so as to form a bevelled margin. A piece of flannel is then placed round the limb, or a simple roller is applied, and then a bandage is neatly and firmly carried from the toes to a distance above the joints between which the fracture is situated, and closely embracing the mill-board. This, on drying, makes a very convenient apparatus, light and strong, and in order to increase its strength and to keep the bandage from becoming unravelled, a thick coating of clarified gum is pasted over the bandage. The starched bandage which is in general use at University College is applied in much the same manner, coarse pasteboard soaked in starch being used, and the limb being surrounded by an even layer of cotton-wool before this is applied. This being elastic, avoids the danger of compression which might ensue when this treatment is followed, as it often is, in the case of recent fractures; and the apparatus has the advantage, when thus applied, that it can, if necessary, be split up by a strong pair of pliers, and its width curtailed, while its efficacy for support can be re-established by the application of tapes or a fresh bandage. With one of these forms of permanent apparatus it is almost invariably the custom to treat fractures after union has taken place, and in many instances where the displacement is not great and the extravasation slight, recent fractures are also treated in this way. In the case of the bones of the leg, a junk is sometimes slung in a "Salter's swing" and the limb placed in it for a few days, until all swelling and bruising have disappeared. A solution of silicate of potash is sometimes preferred to either of the above-named materials.

To return, then, to the consideration of the fractures of the various bones and the usual plans for their treatment. In London hospitals the general method adopted in cases of fracture of the shaft of the humerus is to put the arm up in four well-padded wooden splints tied together by two pieces of bandage which are made to encircle them, one above and one below, and the forearm, being supported by a sling round the neck, gives sufficient extension to ensure a good position of the broken ends. The fingers and forearm may be left unbandaged, unless there is a tendency for these parts to become swollen, and this treatment is usually continued until union has taken place, but the plaster-of-Paris bandage can be applied as soon as all swelling has subsided. This form of treatment can be used in all cases of fracture of the shaft, except those of the condyles or of the lower end of the bone, for which a rectangular wooden splint is almost always resorted to, with or without three additional flat splints to encircle the humerus, the one arm of the right angle being placed along the front of the forearm, and the other along the anterior aspect of the humerus. Any immovable apparatus is disapproved of in this locality on account of the desirability of making early movement in the elbow-joint, which generally is more or less injured when the accident takes place, and is therefore liable to become stiff if passive motion is not commenced at an early stage.

The old plan of treatment of fracture of the olecranon was to put a long straight splint on the anterior aspect of the arm and thus keep it fully extended, whilst the fragments were brought as nearly as possible into apposition by a figure-of-eight bandage. But when, by the action of the triceps, the upper portion of the ulna was drawn a long way up the arm, this plan was not found to give very good results, which answered, however, sufficiently well when the fibrous covering of the bone held sufficiently together to prevent any great separation of the

parts. Accordingly, the plan which has been successfully carried out in the case of the patella has been tried for the ulna, and the parts brought closely together by a silver wire passed through holes drilled obliquely down from the surface of each fragment. Under the antiseptic system this mode of proceeding has been attended with remarkable success in the few cases which have been reported, but it remains to be seen whether it is capable of being more generally followed.

A couple of well-padded, straight, and flat wooden splints are generally all that is required to keep the bones of the forearm in position when fracture takes place in the shaft of one or both, but many plans are in use for correcting the deformity in the injury which goes by the name of "Colles's fracture." Some surgeons use these same splints, and by a turn of the bandage which keeps them in position, passed over the hand, maintain it at an angle downward to the side of the ulna, and obtain satisfactory results. Another very useful apparatus, by which the deformity is more easily corrected, is that invented by Dr. Gordon, of Belfast, who denies that impaction of the broken ends of the radius is of common occurrence, and corrects the deformity "by traction on the hand or pressure on the fragments, placing the hand in the prone position, then applying to the anterior surface of the forearm a splint to which a wooden conical or triangular piece is so attached that the external border of the splint projects beyond it; and on the back of the forearm a straight splint more thickly padded over the wrist than over the forearm," the whole to be fixed by two straps of webbing, and not by bandage. A more convenient and less complicated method in common use is a pistol-shaped splint applied to the back of the hand, with or without a short straight splint to the front of the forearm, and not extending beyond the wrist; the two being kept in position by a bandage.

Passing to the lower limbs, and to the fractures which occur in the femur, the plan of treatment usually followed in London hospitals is by one of the two forms of long splint reaching from the axilla down to the foot, and applied with or without shorter splints surrounding the thigh. When these are applied the foot is fixed by bandages to the lower end of the splint, and to an iron foot-piece which runs out at right angles to it, the form of splint known by the name of the French surgeon Desaulx, and this is secured to the body by a band passing round the waist, and runs up on the outer side of the body to the axilla, having a fork cut in its upper extremity for the purpose of giving a secure *point d'appui* for the perineal band, as it is called, by which traction is made. On this band are threaded three short flat splints, the upper ends of which are cut obliquely so as to fit the line of the groin, and these, with the long splint, surround the whole thigh, and are kept in position by one or more pieces of webbing. The whole having been properly adjusted, traction is made by tightening the perineal band, which, by passing over the upper end of the long splint round the groin and behind the nates, causes extension of the whole limb, and brings the fractured surfaces into close and accurate apposition. The shorter splints are, however, very frequently dispensed with, and then extension is effected by means of a weight applied with strapping to the leg and passing over the end of the bed, where an apparatus is fixed with a rest, over which the cord attaching the weight of seven to nine pounds is passed; and to further the effect of extension the lower end of the bed is slightly raised by blocks, so that the weight of the body may act in a manner to extend from the opposite direction. A patient thus treated is usually kept in bed for from four to seven weeks, and then one of the forms of immovable apparatus is generally applied, plaster-of-Paris being less frequently used in the case of the thigh on account of the great weight which a splint made with this material necessarily involves. With very young children the best results are often obtained by using a weight to the leg as above described, whilst to secure

the limb from movements during sleep, and to keep the fragments in good position, a sandbag is placed on either side of the thigh, and another laid across the seat of the fracture; and further to prevent the patient from slipping down and so nullifying the influence of the weight, a band is passed behind the back from which two loops pass over the shoulders, and this is tied beneath the bed or secured to its upper end. One of these forms of treatment suffices in almost all fractures of the thigh-bone, but there are some in which the broken ends cannot be kept in position by any such means, and this happens particularly when the break occurs a short way below the trochanters, and the upper fragment is drawn upward and inward by the action of the psoas. For these cases the most frequent apparatus used is Earle's bedstead, which allows the patient to lie flat on his back, but the foot being secured on the injured side to a foot-piece, the knees are bent over the raised portion of the bed, which thus forms a double inclined plane, and traction is kept up by the weight of the body, the knee thus becoming practically a fixed point. Many other ingenious modes of effecting the same results have been invented and are occasionally used, but they are not in general use, and are only required in exceptional cases; such, for instance, are the methods of placing the limb in a wire support, without splints, and making extension by a weight attached to the foot and passing over a pulley, which is placed at some height and distance from the end of the bed, or the splint known by the name of "Thomas," which consists mainly of a couple of parallel iron rods united at both ends, the upper being secured round the pelvis and the lower to the foot, whilst a bandage passes round the whole apparatus and gives support to the lower part of the limb.

The treatment of fracture of the patella varies in detail at almost every institution, but the main points are to reduce the effusion into the synovial membrane of the knee-joint, by which the primary separation of the fragments is mainly produced and maintained, and then to bring the two surfaces as nearly as possible in apposition. The first object is attained by raising the limb to an angle with the trunk on pillows, junks, or other apparatus, and applying evaporating lotions to the joint, and the second, by the use of bandages applied in various fashions, strapping, to which is sometimes attached a weight, which, passing over the foot, is intended to drag down the upper fragment and to act counter to the retraction of the quadriceps extensor. Some surgeons still use Malgaigne's hooks, but they are objectionable on account of the risk of inducing erysipelas. The operation of wiring together the fragments has been already alluded to, and has now been performed in a considerable number of instances, but the danger, even with the utmost aseptic precautions, is sufficient to deter surgeons from recommending the operation, especially when the accident occurs, as it most frequently does, in persons past the healthiest period of life, and also considering the very useful limb which is obtained by patients who are willing to submit to a prolonged course of treatment by simple means. Where the separation of fragments has taken place after fibrous union between the two ends of bone, the operation has been resorted to in several cases with more or less satisfactory results. Where splints are used for the treatment of fractures of the bones of the leg, those which bear the name of Cline are perhaps most frequently had recourse to. They consist of two pieces of light pine-wood roughly hollowed out and shaped to embrace the outer and inner surfaces of the calf, ankle, and foot, a round hole being cut for the malleolus in each. These are padded with tow or cotton-wool, and are fixed to the foot by pads and bandages, whilst they are secured round the leg by two pieces of broad webbing. Other surgeons prefer to support the back of the limb, and for this purpose use three flat deal splints to which a foot-piece is applied, and these are kept in position by webbing and strapping or bandages.

Whatever form of splint is used, the custom is almost invariable of swinging or raising the limb, either by junks or by the use of "Salter's swing," which allows the patient to exercise more movement of the body without disturbing the injured extremity. In some cases where the swelling is not great, the limb is placed in plaster-of-Paris, by laying strips of blanket soaked in the plaster on either side of the leg, and bandaging with muslin into which the dry plaster has been rubbed, cotton-wool being used, or, as some prefer, a flannel bandage, to guard against the risk of subsequent swelling. For Pott's fracture, where ecchymosis forbids its immediate treatment by some immovable apparatus, the practice recommended by the Dublin surgeon is usually adopted, namely, to place a single flat wooden splint upon the inner side, with a thick pad over the inner malleolus, and to secure to this the foot below and the leg above by a light bandage.

The same apparatus suffices in the treatment of compound as in simple fractures, the more so as the wound is almost invariably treated on antiseptic principles, more or less strictly carried out in the manner of Professor Lister. Some surgeons, however, still adhere to the use of "Assalini's fracture-box," a weighty and somewhat cumbersome machine, whilst others prefer MacIntyre's splint, which has the advantage of being more easily cleaned, and is thus less likely to become a medium for conveying or retaining the germs of contagious diseases.

Progress of Medical Science.

ANEURISM IN THE GALL BLADDER.—At a recent meeting of the Society of German Physicians in Prague, Dr. Chiari presented a specimen of aneurism in the gall-bladder. The patient had died of melæna. At the autopsy the œsophagus, stomach, and intestines were found filled with partly fluid blood. About two fingers' breadth below the pylorus, in the wall of the duodenum, was a fistula, closed with a blood-clot, leading into the gall-bladder. The latter contained about a dozen calculi. At its lower part was seen an aneurismal dilatation in the course of the right hepatic artery measuring one inch in length by about half an inch in width. Death had resulted from a rupture of this sac. Careful search revealed a second aneurism protruding into the gall-bladder. It was the size of a pea and arose from a branch of the gastro-duodenal artery. There had been an inflammation of the gall-bladder with ulceration, by which the arteries had been laid bare, and the aneurisms resulted from the blood-pressure upon the exposed arterial walls. —*Wiener Med. Wochenschrift*, February 3, 1883.

TREATMENT OF VASCULAR TUMORS WITHOUT OPERATION.—Dr. Fiorani has treated several cases of telangiectasis successfully by the external application of corrosive sublimate in collodion (three parts in twenty). He applies four layers of the substance over the tumor, and a little beyond, with a camel's hair brush. On the fourth day the edges are a little raised, and then a second application of four layers is made. This is repeated every four days until the swollen edges have become depressed. After the crust falls off, the surface is seen to be somewhat sunken and of a pinkish color, which gradually changes to a normal hue. The procedure is entirely painless. It is to be employed only where the angioma is raised but a line or two above the surface. —*Allgem. Med. Central Zeitung*, January 3, 1883.

THROMBOSIS OF THE BASILAR ARTERY.—Professor Leyden (*Allgem. Med. Central Zeitung*, January 20, 1883) relates two cases of this rare affection. The thrombosis results from arterial sclerosis, with consequent dilatation, or from embolism. In the latter case the embolus is usually lodged in one of the vertebral arteries. The changes in the vessels are usually due to syphilis. Ley-

den divides the symptoms into local and general. To the former, due to changes in the pons and medulla, belong paralyzes, difficulty of deglutition and of speech, and a low temperature. The paralysis may be of the face and extremities on the same side, of the face on one side and the extremities on the other, or of the oculo-motor nerve on one side and of the facial muscles and extremities on the opposite. This points to a lesion in the crura cerebri near the pons. To the general symptoms belong stupor, somnolence, delirium, and sopor. They depend upon disturbances of the circulation, induced through closure of the basilar artery. Choked disc is a symptom sometimes present and due to the same cause.

MEDICATED GELATINE IN THE TREATMENT OF SKIN DISEASES.—Dr. Pick speaks highly of medicated gelatine in the local treatment of various skin diseases. It is a clean and convenient dressing, obviating the necessity of bandages or plaster to retain the application. After a bath the patient applies the gelatine, melted in a water bath, with a brush, and after it is dry paints over it a thin coat of glycerine. The latter prevents cracking and chipping off of the dried gelatine, and also keeps it flexible, so that the joint movements are not interfered with. The following is the mode of preparing the medicated gelatine: Dissolve fifty parts of gelatine in one hundred parts of distilled water in a water bath. Then add the medicament in the desired proportion, stirring constantly. Then set the mixture aside and, when cool, wrap in oiled paper. The patient is instructed to melt a piece of this gelatine cake in a saucer set in hot water and, when fluid, to apply with a camel's-hair pencil to the diseased surface. When it is desired to make a fresh application, the patient takes a warm bath and the old dressing is washed away. —*Allgem. Wiener Med. Zeitung*, February 13, 1883.

TREATMENT OF NEURALGIC METRORRHAGIA.—Uterine hemorrhage, occurring in connection with lumbo-abdominal neuralgia, is a condition which is pretty generally recognized, and one for which treatment is, as a rule, unsatisfactory. A writer in the *Revue Méd. Chir. des Mal. des Femmes* claims to have employed with success the tincture of aconite in repeated doses. The only indication for its use is the establishment of a relation between the neuralgic exacerbations and the return of hemorrhage. Even in cases depending upon actual lesion of the uterus, the writer asserts that we can always obtain a favorable remission, if not a permanent cure. The tincture is given in drop doses, in a teaspoonful of water, every fifteen minutes for six hours. No food is to be taken in the meanwhile. On the following day, if the symptoms are ameliorated, the aconite may be repeated in the same dose. If there is no improvement the dose is to be doubled. The maximum daily dose necessary to arrest the hemorrhage is said never to exceed forty-five to fifty drops. But this is an amount of aconite that might give rise to serious symptoms, and the effects of the drug should be very carefully watched.

ANTISEPTIC THORACENTESIS.—In the *Revue de Chirurgie* for January, 1883, Dr. Hache reviews at length the various operations for the removal of pus from the pleural cavity. A comparison of the results obtained in the different modes of procedure leads him to prefer that which is conducted in strict accordance with the rules of Lister himself, even to the eight layers of gauze and the mackintosh. The following are the rules by the strict adherence to which he thinks the greatest success may be obtained: 1. The operation and the subsequent dressings should be performed under the most vigorous antiseptic precautions. 2. The incision should be large and permit of the complete evacuation of the contents of the pleural cavity. The operation should be undertaken as soon as the diagnosis is made. 3. A single washing out of the pleural sack should be made, unless in exceptional cases. A large drainage-tube is to be inserted, and removed only when the discharge has nearly ceased for

several days. When conducted in this way, Dr. Hache favors the operation as leading to a more certain and speedy cure than do the old methods. Since such scrupulous attention to minutiae is required to ensure the success of the procedure, it would seem to be better to transfer it to the domain of surgery.

TYPHO-MALARIAL OR CONTINUED FEVER.—Dr. R. D. Webb concludes a paper in the April number of the *American Journal of the Medical Sciences* as follows: "Seeing, then, that fevers are so closely allied generically, and that even when separated into species, there are striking resemblances; that pathological researches do not establish a constant anatomical lesion, which is pathognomonic of any one of them; and that ulceration of Peyer's glands (claimed as characteristic of typhoid fever) is frequently found in other diseases, we are justified in claiming that a continued fever, occurring under circumstances which point to a miasmatic origin, although it may present many of the vital phenomena of the typhoid fever, and occasionally its recognized anatomical lesion, is still malarial fever. There remains, to his mind, but one other explanation of these continued fevers, viz., that they are to be regarded as atypical typhoid fevers, originating *de novo*. But, admitting the origin, *de novo*, of typhoid fever from animal miasm, and that possibly it may have thus originated in the example he has given, even the warmest advocate of this view will be unable to bring those sporadic, isolated cases which occur again and again in malarial, but otherwise salubrious and healthy country localities, within the rôle of such instances as are claimed as establishing this mode of origin. The natural conclusion, taking all the facts into consideration, is that they are malarial fevers of a typhoid form, using the term typhoid, not in a specific sense, but as indicating a typhoid condition of the system.

GASTROSTOMY, ŒSOPHAGOSTOMY, AND INTERNAL ŒSOPHAGOTOMY.—Operations on the internal organs of the body have become much more common than they were formerly, and in recent years the stomach has been very frequently operated on with the view of counteracting the effects of Œsophageal obstruction. Dr. Morell Mackenzie, in the *American Journal of the Medical Sciences* for April, 1883, analyzes the cases of this character which have been already published, and gives an account of two new cases. He finds that gastrostomy has been performed 81 times, and that death occurred from shock in 27 or in 24.6 per cent.

The advantages of gastrostomy are: 1, that it can be carried out with comparative ease; 2, that there is very little risk in the steps of the operation itself, especially if done in two acts separated by a proper interval of time; 3, that there is almost entire certainty of being able to effect the object aimed at, which is the establishment of an alimentary fistula altogether beyond the seat of stricture; and 4, that the fistula is hidden from sight. The only disadvantage is that gastrostomy still yields a high percentage of deaths. Twenty-six cases of Œsophagostomy are analyzed; of these 16 died within a fortnight, and 7 died from shock.

The advantages claimed for Œsophagostomy are: 1, that it is attended with comparatively little shock; 2, that it facilitates subsequent dilatation of the stricture; while the disadvantages are that the operation is a very difficult one, and attended with considerable danger from its proximity to so many important structures, and there is great uncertainty in any given case whether the opening in the Œsophagus can be made below the stricture; and finally a discharging fistula in the neck is a conspicuous disfigurement.

Seventeen cases of internal Œsophagotomy are analyzed, and the following advantages claimed for this operation: 1, that it is attended with an inconsiderable amount of shock; 2, that if the stricture can be thoroughly divided, gradual dilatation can be carried out, and a cure thereby effected; 3, that the procedure involves no ex-

ternal wound. The disadvantages of Œsophagotomy are: 1, that it can only be safely performed in cases where it is still possible to pass a bougie; 2, it is often difficult to pass all the strictures; 3, in many cases the walls of the Œsophagus are so thickened that limited longitudinal incision does not relieve the obstruction; 4, the actual danger in the operation is far from inconsiderable.

THE USE OF IODINE AS A STOMACHIC SEDATIVE.—The employment of iodine for the relief of the vomiting of pregnancy has been somewhat in vogue for a number of years. And while the success attending its use has been pointed out with more or less enthusiasm, its exact value has never been established. Dr. T. T. Gaunt (*American Journal of the Medical Sciences* for April, 1883) has for a number of years been employing the compound tincture of iodine in drop doses in nearly all forms of emesis, and reports thirteen cases of the most varied character, in all of which vomiting was promptly arrested by the use of this drug.

PERINEPHRIC ABSCESES.—Prof. Dr. John B. Roberts (*American Journal of the Medical Sciences*, April, 1883) believes that purulent collections in the cellular and adipose tissue surrounding the kidney are very properly termed perinephric, or circumrenal, abscesses. It has recently become somewhat customary to speak of them as perinephritic abscesses, but Dr. Roberts believes that perinephric is etymologically the more correct adjective.

The early recognition of the existence of perinephric abscess, and the determination of its relative position with regard to the kidney is important, as the promptness and efficiency of operative treatment must depend very much upon the early discovery of the exact position of the abscess. The author arbitrarily divides the perinephric celluloso-fatty tissue into six tracts. The upper, middle, and lower anterior; and the upper, middle, and lower posterior tracts. There is, of course, no sharp definition between these regions, which are used to conveniently indicate the location of the disease.

It may be premised as an axiomatic truth that, although there may be pains radiating in various directions, anterior inflammation will give rise to pain especially in the front or side of the abdomen, posterior lesions to pain in the loin. Tenderness upon pressure, œdema over the abscess and pointing will be similarly exhibited. The swelling, the tumor-like outlines, and the feeling of resistance to palpation will naturally be the more evident in anterior lesions because the tissues between the disease and the surface are flaccid. Involvement of the chain of sympathetic ganglia, situated along each side of the spinal column, would occur in posterior lesions only.

The following tabular statement of symptoms is given to assist in the localization of perinephritis and perinephric abscess:—

All anterior regions.—Pain, tenderness, swelling, œdema, and pointing in front and side of abdomen. All posterior regions.—Pain, tenderness, swelling, œdema, and pointing in loin. Upper tracts.—Pleuritic friction, pleural effusion, empyema, expectoration of pus; dyspnoea; suprarenal involvement; solar plexus involvement. (On right side.) Bilateral œdema of legs; jaundice; fatty stools; persistent vomiting; rapid emaciation; ascites. Middle tracts.—Albuminuria and casts; suprapubic, scrotal, or vulvar pain or anæsthesia; suppression of urine; uræmia; pus in the urine; œdema of scrotum or varicocele (especially on left side). Lower tracts.—Flexion of hip; pain or anæsthesia of front, inside or outside of thigh; retraction of testicle; pain at knee; scrotal or vulvar pain or anæsthesia, without accompanying albuminuria; unilateral œdema of legs; abscess or sinus near Poupart's ligament; constipation (if left side); involvement of chyle receptacle (if right side).

THE GERMICIDE VALUE OF CERTAIN THERAPEUTIC AGENTS.—Dr. George M. Sternberg, in the *American Journal of the Medical Sciences*, April, 1883, has made a long series of experimental studies as to the germicide value of certain therapeutic agents on various forms of bacterial organisms. In his experiments on the micrococcus of gonorrhoeal pus, he found that, in general, those reagents which destroyed the vitality of the micrococcus from pus are destructive of other organisms of the same class; and their relative value as germicides is not changed when a different micro-organism is used as the test of this value. Moreover, the reagents which were found to be practically valueless as germicides in the first series of experiments, *e.g.*, ferric sulphate, sodium sulphite and hyposulphite, boracic acid, etc., proved to be equally without value when the test was extended to other micro-organisms of the same class. But the reagents found to possess decided germicide power have, in some cases, a different value for different organisms. In other words, the vital resistance of different bacterial organisms to the reagents in question is not in all cases the same. Nevertheless, the comparative germicide value of the reagents tested is the same for the several test-organisms, and, allowing certain limits for specific peculiarities, it is safe to generalize from the experimental data obtained in the practical use of these reagents as disinfectants. But it must be remembered that the resisting power of reproductive spores is far greater than that of bacterial organisms in active growth (multiplication by fission), and the data obtained for the latter cannot be extended to include the former. The *antiseptic* value of the reagents tested depends upon their power to prevent the multiplication of putrefactive bacteria, and this is not necessarily connected with germicide potency.

DISINFECTION OF THE STOOLS IN TYPHOID FEVER.—The importance of the thorough disinfection of the stools in typhoid fever is, to those who believe in it at all, so great, and its practical results in the control of the extension of the disease are so manifest and direct, that any additional data as to the best methods of employing disinfection cannot fail to be of interest. On the other hand, there are quite as many other physicians to whom the subject appears to have no importance whatever. These latter either do not believe in the necessity of the disinfection of enteric fever stools, or else they regard it as of so slight moment that it matters not practically whether it be attended to or not, or, finally, whilst professing to recognize its importance, they adopt in practice imperfect or incomplete measures to accomplish it. Indeed, it may be regarded as the exception to the rule, rather than the rule, both in private practice and in hospitals, to systematically and thoroughly disinfect every stool, even in well-characterized cases of typhoid. Both of these classes of physicians will be interested in a paper on this subject published by Dr. James C. Wilson, in the *American Journal of the Medical Sciences* for April, 1883. He shows that although the nature of the germ that gives rise to enteric fever is unknown, many facts in its natural history are established by abundant proof. Of these the following have a direct bearing upon this subject: 1. It is invariably derived from a previous case of enteric fever. 2. It is eliminated with the fecal discharges. 3. It is not capable of producing enteric fever at once in susceptible persons exposed to it, but must undergo changes outside the body before it acquires this power. 4. It retains its activity in favorable situations for a lengthened period, the requirements to this end being decomposing animal matter, especially fecal discharges, and moisture. 5. In such situations it is capable of reproducing itself.

TRIGEMINAL NEURALGIA RELIEVED BY LIGATION OF THE COMMON CAROTID ARTERY AND NEURECTOMY.—Dr. Ferdinand H. Gross publishes in the *American Journal of the Medical Sciences* of April, 1883, a condensed clinical history, extending over nine years, of a case of this disease, with an account of the various

remedial measures undertaken for its relief. The result of the operative treatment may be summarized as follows:—

First.—The effect of the ligation of the common carotid artery was immediate relief in the domain of the first and second divisions of the trigeminal nerve: the period of immunity from pain in the second division being fully two years, while in the first division the pain has never returned, the relief there being probably permanent, and can only be accredited to the carotid ligation. The effect of this operation upon the third division of the nerve was too transient to count for anything.

It should be added that no impairment of intellect has followed the ligation. After the lapse of nearly two years and a half no disturbance of brain functions has been noticed either by Dr. Gross or the patient, or by any of those who are habitually associated with him.

Second.—The first neurectomy of the inferior dental nerve, eight months later, resulted in a period of relief from the neuralgia of about one year and three months—to remain within safe limits.

Third.—The last two operations, *viz.*, the neurectomy of the superior maxillary and the repetition of the operation upon the inferior dental nerve, were performed within two months of each other, September 14th and November 11th, respectively, and may be considered together. The result thus far is entirely satisfactory, the patient being now, three months later, completely relieved of the neuralgia.

SYPHILIS OF THE EYE AND ITS APPENDAGES.—Dr. Leartus Conner publishes in the *American Journal of the Medical Sciences* for April, 1883, a paper bearing on this subject, in which the following points are emphasized:—

First.—The study of specific ocular diseases is helpful in the diagnosis of certain obscure cases otherwise difficult to make out satisfactorily. Thus, a specific iritis will at once set at rest all doubts as to the origin of a series of indefinite general symptoms which have annoyed the patient and puzzled the doctor.

Second.—The careful attention to these cases is the only method by which, in many cases, the eyes can be saved intact during the course of the disease. Surely, when such attention can save eyesight in some cases, it is criminal not to give it to every case.

Third.—The study of these lesions calls for the most searching examination of the entire organism. Especially is this true of such affections as cannot be distinguished from like diseases of the eye due to far different causes. Thus, if the early treatment of a dacrocystitis be simply local, it is sure to fail if it be of specific origin. Hence, the only chance to avoid failure lies in such an examination as will reveal its specific nature. The same remark applies with even greater force to many other specific diseases of the eye, as will be gathered from his brief review. From this it follows that, in every eye case, the only safe practice is to constantly entertain the possibility of specific infection.

Fourth.—The treatment of every specific case calls for constant watchfulness of the eyes with the ophthalmoscope, otherwise lesions impossible to repair may be established before the practitioner is aware of their existence or of any danger. Perhaps in no class of troubles is it more apparent that the general and special knowledge of morbid phenomena need to be constantly combined in one person. The special practitioner needs to be a general one, and the general practitioner a special one.

HOLMES ON RICORD.—"I think life has not yet done with the vivacious Ricord, whom I remember calling the Voltaire of pelvic literature—a skeptic as to the morality of the race in general, who would have submitted Diana to treatment with his mineral specifics, and ordered a course of blue pills for the vestal virgins."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 21, 1883.

THE QUININE OF THE POOR.

UNDER this attractive title Dr. Ugo Bassi describes the result of his experience with resorcin in the treatment of intermittent fever. He reports twenty cases in which he had used this remedy. Of them seventeen were entirely cured; two of the remainder were old and obstinate quartan types, while the third patient was in very unfavorable hygienic surroundings. In one case the symptoms returned and were not removed again either by resorcin or quinine. It required only two or three doses of the drug to effect the cure in the successful cases. The doses given varied between thirty and forty grains. Larger amounts were not found to do any good. The peculiar advantage of resorcin in Dr. Bassi's opinion is its cheapness.

Resorcin is a drug of which much has been written lately, especially by foreign observers. It was first obtained in 1864 by Hlasiwetz and Barth from galbanum resin by fusing it with potassa. It is now best prepared by fusing potassium benzol-disulphate with caustic potassa. Resorcin is a substance closely allied chemically and in its physiological action with phenol, its formula being $C_6H_6O_2$, while that of phenol is C_6H_5O . It is claimed, however, to be much less poisonous and much more agreeable in taste and smell.

Among the most recent contributions regarding its therapeutical uses is an article by Dr. C. Fürst, of Vienna, upon resorcin as an antipyretic. This physician states that resorcin was given in more than three hundred cases of puerperal fever occurring in the service of Professor Braun. It was administered in doses of three grammes (forty grains) dissolved in water, repeated when necessary. The result was almost without exception to bring down the temperature nearly to the normal. After a few hours there was a rise again, so that a dose given, for example, in the evening had to be repeated in the morning. The temperature fall was usually accompanied with profuse perspiration.

Dr. A. Skibnevsky, of Moscow, has used injections of resorcin in erysipelas with good results. From ten to twenty injections of the five per cent. solution were given, with the result of lessening very rapidly the fever and checking the progress of the disease. In the *Deutsche Medical-Zeitung*, for 1882, page 347, are recorded similar favorable results obtained by Dr. Bogusch.

Dr. Justus Andeer, of Wurzburg, has experimented with resorcin externally applied, and finds that it is not

absorbed by the sound skin. He made a fifty per cent. vaseline ointment and used it in the treatment of some cases of anthrax. The ointment was applied to the pustules and covered with a gauze bandage. The results were remarkably favorable, the pains disappeared and the diseased parts speedily assumed a healthy appearance. Dr. Andeer also states that the drug does not cause hæmaglobinuria like naphthol, and develops none of the poisonous symptoms caused by its congener, carbolic acid.

THE INFECTIOUS NATURE OF PNEUMONIA.

At a recent meeting of the Berliner Verein für Innere Medicin (*Allgem. Med. Central-Zeitung*, February 3, 1883), Dr. Leyden exhibited some preparations of micrococci taken from a patient with pneumonia. They were obtained by inserting a Pravaz syringe into the hepatized portion of the lung, and were prepared by the dry method and stained with methylene blue. The parasites were of an oval shape, usually in pairs, but sometimes united in a chain of three or four links. The patient died, and an autopsy was made six hours after death. As soon as possible portions of the inflamed lung-tissue were removed and placed under a Hartnack immersion lens, without staining. The micrococci were readily perceived. In stained preparations the parasites were seen to be most numerous in the portions of red hepatization, but much more scanty in the parts which had passed into the condition of gray hepatization. Dr. Leyden stated that he had withdrawn blood from the diseased portion of lung in two other cases of pneumonia, but without result. He explained the absence of micrococci in these cases by the fact that the disease was in both instances in the stage of resolution, and hence it was to be expected that the parasites should have been absent, or present in very small numbers. The speaker gave to Klebs the credit of having first described these organisms in 1875. His article, however, attracted but little attention at the time, owing perhaps to the fact that his investigations were apparently not conducted with efficient exactitude.

THE ETHICAL CRISIS.

THERE is little doubt that the activity displayed by those holding diverse views regarding the question of ethics is leading many who heretofore have given little thought to the matter to begin a careful examination of the subject for themselves. A series of commentaries by Dr. Austin Flint on the Code of the American Medical Association are in process of publication in the columns of our valued contemporary the *New York Medical Journal*. In his remarks concerning the portion of the Code that relates to consultations, Dr. Flint claims that the "exclusive dogma" clause of the Code was directed not so much against the homœopaths, as against the steam doctors, or Thomsonians, etc. He further claims that the American Code was not intended "to interfere with the practice of medicine, under any circumstances, in the cause of humanity." He says that "the restrictions of the Code are in nowise inconsistent with the demands of humanity in cases of emergency." This view of the case is certainly a novel one, and one that, so far as we are aware, has never been taken by any of the organized bodies that

have heretofore accepted this Code. If this is the correct view, it is greatly to be regretted that Dr. Flint had not brought it to the notice of the profession at an earlier date. Curiously enough he goes on to say that "a practice based on an exclusive dogma" is not a proper ground on which to refuse to "meet practitioners in consultation." "Any physician has a right either to originate or adopt an exclusive dogma, however irrational or absurd it may be." Dr. Flint hopes that the American Medical Association will adopt such modifications in the phraseology of this section as will place restrictions on consultations, not on the ground of doctrines or forms of belief, but on separation from and avowed antagonism to the medical profession." If Dr. Flint would personally urge this matter on the attention of the Association at its approaching meeting, we have little doubt that much could be effected in the way of restoring harmony in the profession. A much better and lasting solution of the question, however, would be arrived at if the Association itself would rescind all formal codes, and simply urge the profession to establish such ethical regulations as local circumstances might render most expedient. If the American Medical Association would for the future strictly confine its deliberations to the consideration of purely scientific matters, science would be the gainer and propriety would lose nothing.

CAN A FŒTUS BE POISONED WITH ALCOHOL THROUGH THE BLOOD OF THE MOTHER?

WE have received from Dr. William A. McDonald, of Lynn, Mass., some interesting testimony bearing upon the question of the effect upon the fœtus of alcohol taken by the mother. It appears that Dr. McDonald was called upon to deliver a woman who had been drinking for some ten hours, and who, when labor began, was profoundly intoxicated. The child was large, weighing about twelve pounds, and the pelvis small. Forceps had to be resorted to. The infant lived for only three hours, and died, it is believed by our correspondent, from alcoholic poisoning. The use of the forceps and the death of the child were made the pretext by a Catholic priest for circulating stories against Dr. McDonald's professional skill and moral character. A suit was brought. Four local physicians testified for the defendant and all agreed, as Dr. McDonald writes, that "There is no quantity of alcoholic stimulants taken into the mother's system that can in any way affect her unborn child, or affect it after it is born. That the perineum is never lacerated by the passage of the child's shoulders in parturition, and that forceps, when properly applied to the child's head in delivery, cannot slip under any applied degree of traction, however great."

It is regarding the first point that we are furnished some interesting testimony. The following inquiry was sent to Drs. John C. Dalton and William B. Carpenter: "If during the progress of labor, and at the moment of delivery, the mother is deeply intoxicated from the excessive use of alcoholic stimulants, would the new-born infant suffer in consequence, or show any symptoms of alcoholic poisoning?"

To this Dr. Dalton replied: "I would say that if the mother were deeply intoxicated at the beginning of

labor, I should not be surprised to find the new-born infant affected in consequence. As the fœtus derives its nourishment, by absorption through the placenta, from the blood of the mother, I see no improbability in alcoholic substances being absorbed by the same channel, so long as the placenta is adherent, and the placental circulation going on."

Dr. W. B. Carpenter answered: "I cannot profess to speak with any authority upon the question you have submitted to me, for I am not aware of any experiments (such as have been made with other poisons) on the passage of alcohol from the maternal to the fœtal blood. I can only say that as there can be no question of alcohol received into the alimentary canal being taken into the circulation by transudation through the walls of the blood-vessels of the intestinal villi, there seems every probability of its passage from the maternal blood, through the placental villi, into the fœtal circulation. Though I can see no reason why such passage should take place more actively during parturition than at any other time, I can suppose it to have a much more pernicious effect. For up to the detachment of the placenta, the fœtus is not only deriving *nutriment* from the maternal blood, but is dependent upon the placental circulation for the small amount of *aëration* which it requires to sustain its intra-uterine life. As soon, however, as the child comes into the world, active muscular movement begins, and atmospheric respiration is required to sustain it. The first inspiration, as you are doubtless well aware, is a reflex act, performed through the instrumentality of the nervous system. And it seems to me not only *possible*, but *probable*, that blood-poisoning of the fœtus by alcoholic intoxication of the mother during parturition, may so torpify the respiratory centres of the infant that the ordinary inspiratory movement may not be excitable, and the child be 'still-born.' You do not say whether this was the condition of the infant in the case to which you refer. Supposing it to have been so, my opinion would be that while there is strong ground for believing the death of the child to have taken place through the mother's fault, there would *not* be an adequate basis for a criminal charge against her."

Dr. Carpenter subsequently submitted his views to Dr. B. W. Richardson, who corroborated them entirely.

Despite the opinions of the above eminent savants, we must consider it, in the lack of positive facts, extremely improbable, if not entirely impossible, that the fœtus should be fatally poisoned by alcohol through the blood of the mother. Alcohol is rapidly eliminated from the mother's system, and no great amount can exist in the blood at a time. On the other hand the fatally poisonous dose of alcohol is considerable. There is little doubt that the fœtus could be affected somewhat, but this needs to be better proved. The question deserves further study.

THE PATHOLOGY OF INTESTINAL SYPHILIS.

SYPHILITIC lesions of the intestines are, according to Kundrat, very seldom met with in adults, being more commonly found among the manifestations of hereditary syphilis. Yet even here they are comparatively rare, Kundrat and Marzek having seen but nine instances among two hundred cases of infantile syphilis. In all

of these cases syphilis of other organs was also present. The small intestine appears to be oftener attacked than the large, in the proportion of about four to one. Two varieties of the affection present themselves. In the first the process is essentially localized, and is confined usually to Peyer's patches and the solitary follicles. In the second the disease attacks the entire circumference of the canal. The mucous membrane presents a velvety appearance, and about Peyer's patches is of a dark red color. Little pits are seen in the surface of the patches, giving a cribriform appearance to the part. In the second form little nodules are scattered over the inner surface of the intestines, of the size of a hemp-seed, or smaller. The meconium is thickened and adherent to the wall of the intestine. The peritoneum is usually of a pale red color and presents numerous points of syphilitic growth about the vessels. In more severe cases there is a fibrinous exudation covering the peritoneum.

A diagnosis of this variety of visceral syphilis is evidently a matter of some practical importance. But it is not always possible to make it. As regards the treatment of luetic affections of the alimentary canal, the same general principles which govern all cases of congenital syphilis are applicable to this class of cases.

PATHOLOGICAL SLEEP.

OVER a year ago, M. Gélinau described a peculiar symptom which he called narcolepsy, and which consisted in an abnormal tendency to sleep. The subject excited some interest, and recently M. Gilbert Ballet has contributed several cases, having the same features. The narcolepsy of Gélinau and Ballet, however, is a different thing from the sleeping sickness of Africa, which is apparently a specific and generally fatal endemic disease. Narcolepsy, or pathological tendency to sleep, is a symptom of several different morbid conditions. Ballet classifies them under four heads, viz.: 1. In a certain number of cases the morbid condition is not known. It can only be assumed that the metabolic changes in the brain-tissues are modified, the retrograde process being perhaps too active, or the constructive action too feeble. 2. This condition certainly appears to exist in diabetics, a class in which excessive somnolence sometimes develops. 3. Narcolepsy is observed in connection with various organic diseases, which diseases are related in some way to the sleep-symptom. Camusat has observed it in a patient with heart disease; Bouland, in a case of hepatic congestion; Gélinau, in a case of chronic dyspepsia. In these instances there seemed to be a condition of cerebral congestion. 4. Certain hysterical persons will at times be affected with narcolepsy or attacks of spontaneous sleep. Some of the cases reported as of this nature are rather examples of trance lethargy.

The symptoms of this condition are generally simple. The patient sleeps all night, and is awakened with difficulty. During the day he is frequently overcome with an invincible drowsiness; he dozes at his meals, and falls to sleep after them; he sleeps in the cars, or stages, or whenever he sits down to rest. The appetite may be good and all the bodily functions normal.

Some benefit has been done by treating any coincident disease that may be present and by hydrotherapy.

THE HOLMES DINNER.

THE profession of the city can congratulate itself upon having so happily conceived and successfully carried out the project of tendering Dr. Holmes a complimentary dinner. It is but once in a century that the medical profession raises up to literature an equal to our Boston guest. Since the days of Goldsmith, medicine has had many singers; Akenside has written his beautiful pastorals, Armstrong his robust and prophylactic epic, and Darwin his botanic philosophy and his episodes in vegetable loves. We would claim Keats, if it were fair to do so. Mr. George William Curtis fitly reminded us that New York has had a doctor-poet in Nathan Drake, of whom we may be justly proud. We would be glad to think, as many do, that the late Dr. Holland was sometimes touched with the divine afflatus.

But although the list of the last hundred years is not so very short, it contains no name which can justly rank with that of our Boston anatomist, autocrat, and poet. It is most creditable, therefore, to the profession here that it has shown its appreciation so handsomely and enthusiastically.

The guests of the evening appear to have been satisfactorily entertained in every way. Dr. Holmes's poem discovered the pleasant fact that he has lost none of his old inspiration; but that, even under the ribs of seventy he can kindle a flame as warm and brilliant as in his younger days. The poem was received with an applause and enthusiasm such as is rarely displayed by our dignified Faculty.

News of the Week.

FIFTIETH ANNUAL MEETING OF THE TENNESSEE STATE MEDICAL SOCIETY.—The Tennessee State Medical Society met at Nashville, April 10th, 11th, and 12th, the President, Dr. W. F. Glenn, presiding. About seventy members were present. Dr. Deering J. Roberts, Chairman of the Committee on Arrangements, delivered a stirring address of welcome, defending the Society against the charge that it was a decrepit institution.

The President's annual address was devoted to the subject of the "Immortality of Man," arguing eloquently for the reality of such immortality.

Dr. J. S. Nowlin read a paper upon "Vaccination and Small-Pox." It presented strongly the facts demonstrating the value of vaccination. He thought that special care and skill was required for the preparation of bovine virus. At the close of his paper the Society passed the following resolutions:

Resolved, That this Society does recommend and ask the State Board of Health to immediately institute such measures as will at the earliest possible moment secure a law requiring the vaccination of every infant born in this jurisdiction.

The resident physicians of Nashville gave their visitors a dinner Wednesday evening.

The following officers were elected for the ensuing year: *President*—Dr. A. B. Tadlock, of Knoxville (who said he would rather hold that office than be a Congressman); *Vice-Presidents*—Dr. A. Morrison, of Nashville;

Dr. W. W. Taylor, Dr. C. S. Wright; *Secretary*—Dr. C. C. Fite; *Treasurer*—Dr. D. J. Roberts.

Papers were read by Dr. Tadlock, on "Femoral Hernia;" by Dr. G. W. Davis, on "Induced Abortion." Dr. Grant opened a discussion on puerperal fever; Dr. J. G. Sinclair showed a case of burn of the eye; Dr. W. D. Haggard read by title a paper on "Ovarian Disease," and Dr. S. Lipscomb related some interesting historical reminiscences.

So far as our reports inform us, the Medical Society of the great State of Tennessee during the parturient stress of a two days' session, gave birth to only three written contributions to medical science.

We agree with the late President that man is probably immortal, but we feel less confident as regards the Tennessee State Medical Society. *Deo volente*, it will meet next year at Chattanooga, on the second Tuesday in April.

THE KENTUCKY STATE MEDICAL SOCIETY.—The scientific work of the first day consisted of a report upon "Materia Medica," by Dr. T. J. Greely, and one on "Surgery," by Dr. W. M. Fuqua. During the second day, papers were read on "Obstetrics," by Dr. P. B. Scott, and on "Hygiene," by Dr. Speed. Dr. J. N. McCormack read a report on "Local Boards of Health," which opened a very lively discussion upon the subject of the State Board of Health. Dr. Holland defended it; Dr. Yandell attacked it, and stated that in five years it had received \$12,500 in cash, without making any real return.

The following officers were elected: *President*—Dr. J. N. McCormack, of Bowling Green; *Vice-Presidents*—Drs. J. M. Riffe and G. M. Harwood; *Secretary*—Dr. S. M. Letcher; *Treasurer*—Dr. H. Brown. Dr. L. S. McMurtry tendered his resignation as Permanent Secretary.

Papers were read by Dr. Thomas F. Rumbold, on "Chronic Naso-Pharyngeal Catarrh;" by Dr. W. O. Roberts, on "Head Injuries;" by Dr. J. M. Matthews, on "Diseases of the Rectum."

The Committee on Prize Essays reported that no essay had been reported for them.

On the last day seven papers were read upon various topics.

The Society adjourned to meet next year at Bowling Green, the first Wednesday in May.

A MEDICAL SCHOOL FOR WOMEN at Toronto is talked of, co-education having failed.

THE ONTARIO MEDICAL ASSOCIATION meets in Toronto the first Wednesday in June. The Secretary, Dr. White, is trying to arrange for an exhibition of pathological specimens at the time.

SCARLET FEVER FROM OYSTERS.—Dr. Fred. Eklund, of Stockholm, says that in the juice and parenchyma of oysters he has found two kinds of micro-organisms in great number. One of these, the *plax scindens*, is, we are informed, the determinate cause of scarlet fever.

ST. PAUL is to have a Health Officer, says the *North-western Lancet*; and no doubt the old gentleman needs a little attention, being now in his nineteenth century.

AN EPIDEMIC OF INFLUENZA is prevailing at St. Paul, Minn. It appeared about January 1st and has been steadily increasing in severity.

THE GEORGIA STATE MEDICAL ASSOCIATION holds its annual meeting at Athens, April 18th, 19th, and 20th.

THE JOURNAL OF NERVOUS AND MENTAL DISEASES.—The January number of this journal contains a steel portrait of the late Dr. George M. Beard, with an appreciative notice of that lamented neurologist.

The *Journal of Nervous and Mental Diseases* has been ably and successfully conducted since it was removed to New York and placed under the editorship of Dr. Morton. It most creditably represents neurological science in this country.

PHYSIOLOGICAL INVESTIGATION.—Dr. McKendrick, Professor of Physiology in the University of Glasgow, and Fullerian Professor of Physiology to the Royal Institution of Great Britain, will give at the Institution a course of ten lectures on Physiological Discovery, being a retrospect, historical, biographical, and critical, of the subject. The object of the course of lectures is to trace the progress of physiological research from about the beginning of the sixteenth century to recent times, and more especially along those lines that have led to great results.

THE MISSOURI STATE BOARD OF HEALTH, recently established by legislative enactment, is to be composed of seven persons, to be appointed by the Governor and confirmed by the Senate. Five of the Board are to be physicians in good standing, graduates of reputable medical schools. No special school is designated. The Board is to exercise general supervision over the health of the State, but not over the private practice of physicians. Ten thousand dollars are appropriated to meet expenses.

A LAW TO REGULATE THE PRACTICE OF MEDICINE IN MISSOURI has recently been enacted. It requires every person practising medicine and surgery to register his diploma with the Board of Health. If the diploma is genuine and issued by a reputable school of medicine, the Board issues its certificate upon the payment of a fee of one dollar; said certificate entitles the lawful holder thereof to practise medicine. If not a graduate, and practising medicine in the State for a term of less than five years, he shall submit to an examination as to his qualifications. If his examination proves satisfactory to the Board, upon the payment of a fee of five dollars the said Board shall issue its certificate in accordance with the facts, and such shall entitle the lawful holder to all the rights and privileges. If a diploma is found to be fraudulent, or not lawfully owned by the possessor, the Board shall be entitled to charge and collect twenty dollars from the applicant presenting it. It appears to us that the law will be found a most inefficient one. It will legalize all the five-year quacks, and it contains apparently no machinery for carrying out its provisions.

AN AFFECTIONATE DAUGHTER.—It is said that Mlle. Bernard, the daughter of Claude Bernard, has been fined at Boulogne-sur-Seine, on complaint of her neighbors, for converting her courtyard, garden, parlor, and bedroom, into a kennel for destitute dogs. She felt some reparation was due the canine race for the miseries inflicted on it by her father's vivisections.

DR. JAMES B. BAIRD has retired from the editorship of the *Atlanta Medical Register*. He will be succeeded by Dr. John H. Logan.

NEW FIELD FOR WOMEN PHYSICIANS.—The Russian journals state that General Tchernieff is about to establish a hospital for Mussulman women at Tashkend. It is to be presided over entirely by Russian female physicians.

THE PATHOGENIC MICROCOCCUS OF ERYSIPELAS.—The existence of micrococci in erysipelas has long been known. Dr. Fehleisen, Bergmann's assistant, now announces that they are positively the cause of the disease. He has isolated them, cultivated them on gelatine through fourteen generations. He then inoculated rabbits, and also men, with the pure organisms and produced in most cases a typical erysipelas. The inoculations were made in seven patients who were suffering from lupus, cancer, and sarcoma. One case of lupus was almost completely cured, in another case the cancerous tumors disappeared, in another of fibro-sarcoma the tumor diminished in size. In the other four cases no especial effect on the tumors was noticed.

NEWPORT MEDICAL SOCIETY.—At the Annual Meeting of the Newport Medical Society, held April 3, 1883, the following officers were elected: *President*—Dr. H. R. Storer; *Vice-President*—Dr. Samuel W. Francis; *Secretary*—Dr. W. D. McKim; *Treasurer*—Dr. William C. Rives; *Librarian*—Dr. C. L. Fisher; *Curator*—Dr. S. H. Sears.

THE NATIONAL ACADEMY OF SCIENCES held its Annual Meeting, during the present week, at Washington, D. C.

THE TURN OF THE TIDE: THE KINGS COUNTY MEDICAL SOCIETY ON THE SIDE OF THE NEW CODE.—The Medical Society of the County of Kings held its regular meeting April 17th. The question of action upon the new Code of Ethics came up. The resolutions offered by Drs. E. R. Squibb and Kretschmar were disposed of by laying the whole matter on the table, by a vote of 54 to 35. It was then moved that, in the opinion of the Society, it is inexpedient to discuss this general Code question further for the current year. This motion was carried by a vote of about 48 to 35. The action of the Society was a decided victory for the new Code. The vote to refrain from further discussion of the subject during the current year will strike all as a very sensible act.

COLUMBIA VETERINARY COLLEGE AND SCHOOL OF COMPARATIVE MEDICINE.—Dr. Alexander Hadden has purchased a new site and buildings for the Columbia Veterinary College and School of Comparative Medicine at 215 and 217 East Thirty-sixth Street. A new hospital will at once be erected and the buildings will be enlarged and improved. The college has been growing so rapidly that the old buildings were quite insufficient for the proper accommodation of the students. The Columbia Veterinary College has been the centre of much good work in comparative pathology and physiology, and its present prosperity is amply deserved.

A DOCTOR EXPELLED.—Dr. E. L. R. Thompson, charged with causing abortion, was expelled last Monday from the New Haven Medical Association.

DEATH OF DR. WILLIAM FARR.—Dr. William Farr, F.R.S., D.C.L., Superintendent of the Statistical Department of the Registrar-General's Office, Somerset House,

which he organized in 1838, died April 16th. He was born at Kenley, Shropshire, in 1807, and received his medical education in the universities of Paris and London. He was for a time editor of the *Medical Annual* and *British Annals of Medicine*, and was a frequent and a learned contributor to medical literature. He assisted in taking the census of 1851, 1861, and 1871 in Great Britain, and wrote a considerable portion of the reports of the first two years named. He wrote the annual official reports on the public health, and among his best known works were "The Finance of Life Assurance," "English Life Tables, with Values of Annuities and Premiums for Single and Joint Lives," a new "Statistical Nosology," and a report on the "Cholera Epidemic of 1849." He was chosen a corresponding member of the French Institute in May, 1872. Dr. Farr was one of the pioneers in state medicine.

THE PROCEEDINGS OF THE NAVAL MEDICAL SOCIETY are published in the form of a neatly printed monthly. So far, the society has evidently done excellent work.

AN INTERNATIONAL CONGRESS OF COLONIAL PHYSICIANS will be held at Amsterdam, September 6, 7, and 8, 1883, during the International Colonial Exposition which is to be held at that time. Professor Stockvis is chairman of the Committee of Organization; Dr. Van Leent, Secretary-General. Questions of special interest to physicians living in the colonies, and tropical climates will be discussed.

STRICKER, SPINA, AND THE TUBERCLE BACILLUS.—At a recent meeting of the Medical Society of Vienna, Professor Stricker stated that though he had not followed Spina's work in detail, he believed in its trustworthiness. He thought that Spina had shown that some bacteria of putrefaction can be colored in the same way as the so-called tubercle bacillus.

OUR DENTAL BRETHREN on both sides of the water are becoming a very pushing class. Not long ago several Parisian dentists offered to do dental work free in the municipal hospitals. The Municipal Council, politely refusing this over-liberal offer, reminded the petitioners that it was a principle of true democracy that every man should be paid for his work. New York dentists vent their surplus activities in other ways. A firm in this city, for example, have a large show-window containing a wax figure with moving jaws and a hysterical smile. Above it is the legend: "Acher, Puller, & Filer, French Dentists. No charge for extracting teeth. Come in and have one drawn. Rubber sets, \$1 to \$5."

DRUG-STORE TIPLING.—The Liquor League at Indianapolis, Ind., has inaugurated a movement looking to the suppression of dram-drinking in drug-stores, as it has grown to such proportions as to interfere with the regular retail business. It is said much testimony has been taken, and an effort will be made to compel drug-stores at which liquor is sold in less quantities than a quart to take out a State license.

THE NIGHT MEDICAL SERVICE OF PARIS.—In 1882 there were 6,891 visits against 5,282 in 1879, and 3,613 in 1876, the year in which it was first started. The service contains 658 physicians and 185 sages-femmes.

WOMEN PHYSICIANS IN AUSTRIA.—A young woman of Prague, who had received a medical degree from the University of Zurich, asked permission of the Minister of Public Instruction to have her diploma recognized and to be admitted to the examinations of the Vienna Faculty. This permission was denied, the minister alleging that the practice of medicine by women is not permitted in Austria.

SANITARY STATISTICS WANTED IN ITALY.—The Italian Government has asked for an interchange of vital and sanitary statistics with the Board of Health of this city.

Reviews and Notices.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA at its Thirty-Third Annual Session, held at Titusville, May 10, 11, and 12, 1882. Vol. xiv. Philadelphia: Times Printing House. 1882.

ON opening this volume, we were agreeably surprised by the marked improvement in paper and type which it presents over the previous annual reports of the Society. Of the papers contained in it, the following deserve mention: "Address in Obstetrics," by R. Stansbury Sutton, M.D., of Pittsburg, giving a good bird's-eye view of the present state of abdominal and pelvic surgery on the continent of Europe; but not containing a word about obstetrics; "Reflections of Criminal Lunacy, with Remarks on the Case of Guiteau," by C. K. Mills, of Philadelphia; "The Oleates and Oleo-Palmittates in Skin Diseases," by John V. Shoemaker, of Philadelphia; "A Comparative Study of the Action of Certain Mydriatic Alkaloids," by Edward Jackson, M.D., of West Chester; "On Sympathetic Irritation and Sympathetic Ophthalmia," by W. S. Little, M.D., of Philadelphia; "Powdered Boracic Acid in the Treatment of Otorrhœa," by C. S. Turnbull, M.D., of Philadelphia; "Excision of Cartilage in Nasal Obstruction due to Deviated Septum," by John B. Roberts, of Philadelphia.

INJURIES OF THE SPINAL CORD, WITHOUT APPARENT MECHANICAL LESION AND NERVOUS SHOCK. IN THEIR SURGICAL AND MEDICO-LEGAL ASPECTS. By HERBERT W. PAGE, M.A., M.C. Cantab. Philadelphia: P. Blakiston, Son & Co. 1883. \$4.00.

MR. PAGE devotes the first two chapters of his book to the discussion of concussion of the spine. He combats the generally received view that the spinal cord is subject to serious disturbances or suspension of function from blows which shake it, but do not cause mechanical injury. The spinal cord, he says, is the best protected organ in the body, and is not affected by concussion, as is the brain. In Mr. Page's opinion, the clinical symptoms generally classed under this head of "concussion of the spine," are due to nervous shock, united often with sprains or other injuries of the muscles and ligaments of the spine. Those symptoms of functional disturbance of the cord which are objective and can be demonstrated are, he thinks, due to hemorrhages and mechanical lesions. They are not brought on by a simple shaking of the cord. The author particularly attacks Mr. Erichsen for his too easy acceptance of the concussion theory.

The nature and symptoms of shock are described very well, from a surgical point of view. The author insists upon the larger importance of this physical element in the disturbances from railway injuries.

There is a chapter upon functional or neuro-mimetic disorders which is interesting, although chiefly a compilation from others—a too prominent feature in the book.

The chapter on malingering is more original and better written.

A very useful appendix containing the tabulated histories of two hundred and thirty-four cases is added.

The author states in his preface that although surgeon to a railway company, he is not biassed in his views. Mr. Page, no doubt believes this; but it strikes us that the general tone of the book and the discussions in it are decidedly favorable to railway companies, and that it would be an excellent thing for them, from a business point of view, to see that it is well circulated. We say this, while believing that the author is right in his view as to the importance of nervous shock, and the physical element in railroad injuries. He has undoubtedly shown also that functional disturbance of the spinal cord from concussion is rarer than has been supposed. That it can, and does occur, however, we must still believe.

The book should be examined by all physicians who have to deal with the class of cases treated of.

THE DISEASES OF THE PROSTATE, THEIR PATHOLOGY AND TREATMENT. By SIR HENRY THOMPSON. Fifth London Edition. Philadelphia: P. Blakiston, Son & Co. 1883.

THE present fifth edition of Thompson's well-known treatise has been carefully revised, and, by many new additions, has been brought fully up to date. It may be consulted with profit by student and practitioner, as it embodies the ample experience of a careful observer and the mature judgment of a sound mind.

SUPRAPUBIC LITHOTOMY. By WILLIAM TOD HELMUTH, M.D., New York. Illustrated. 4to, pp. 93. New York: Boericke & Tafel. 1882.

THIS volume is a plea in behalf of the high operation for stone or epicystotomy, on the grounds of its easy performance and comparative freedom from danger. Dr. Helmuth presents his case strongly, and his work may be instrumental in restoring to professional favor a method of cystotomy now but rarely resorted to in calculous affections. With commendable diligence the author has collected statistical data concerning the various methods of lithotomy. From these it would appear that the high operation is followed by the smallest mortality. Helmuth's work deserves to be read and studied by all who are interested in this department of surgery. The mechanical execution of the volume is satisfactory, the paper, type, and illustrations being unusually good.

FORMULÆ FOR HYPODERMIC INJECTION OF CAFFEIN.—Dr. C. Tauret, of Paris, Laureate of the Institute of France, etc., writes us: "I have read in THE MEDICAL RECORD of January 6th, the résumé of my researches on caffein. I seize this opportunity to give you below the exact formulæ that I use for ten hypodermic injections of caffein. First:

R Benzoate of soda		3 grm.	60
Caffein		3 "	00
Distilled water, about		5 "	40

or a sufficient quantity to get ten cubic centimetres.

One cubic centimetre of that solution contains thirty centigrammes of caffein. Second:

R Benzoate of soda		2 grm.	95
Caffein		2 "	50
Distilled water, about		6 "	00

or a sufficient quantity to get ten cubic centimetres.

One cubic centimetre of that solution contains twenty-five centigrammes of caffein."

Two other formulæ are given, but the interest in them is chiefly pharmaceutical.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 28, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

CHRONIC HYDROCEPHALUS WITHOUT ENLARGEMENT OF THE SKULL.

DR. BEVERLEY LIVINGSTON presented a skull and brain with the following history:

"James B—, born in the United States, aged two years and seven months, was admitted to the Nursery and Child's Hospital on February 16, 1883, with his mother, who stated that she was twenty-three years old, had been married three years; that she was one of twins, the first one, also a girl, was born dead, that she was paralyzed on the left side after birth, but recovered, with the result that her left leg is at present smaller and two inches shorter than the right, so she has to walk on the toes of her left foot. The patient, her first child, was born naturally, nine months after marriage. The father is a healthy man; neither parents show any signs of syphilis. Until three or four months old the child seemed healthy, then he was taken sick, but how I could not discover, only that the doctor said he had water on the brain; his mother says he has always been a restless child, who did not sleep well and would have "spells of crying;" he never had any convulsions, but was very dull; he grew like any other child, cut his first teeth when he was about one year old, and he has never had any other nourishment than his mother's milk. The mother at present is a pale, anæmic, poorly nourished woman, and her milk may not have been good, but her second child, now seven months old, born when this one was two years old, has the appearance of a strong healthy baby. The mother cannot say definitely when she first noticed that this child was blind, but assures me that she always thought his eyes were queer; his hearing seems normal, his bowels have been regular, and his urine normal.

"When admitted the child was 76.70 ctm. (2 feet 7 inches) in length, symmetrically developed. The head was only of the average size, being 44 ctm. in circumference, 15 ctm. in the antero-posterior diameter, and 10.75 ctm. in the biparietal; the only abnormal point was that the anterior fontanel was open and would admit the end of the finger. The face was well formed and perfectly symmetrical; the expression was vacant, for the eyes were widely open and the eyeballs wandered aimlessly here and there, the pupils being partially contracted, but equal; they would not respond to light or other stimulant, there was no strabismus or the usual rolling of the eyes downward; he was totally blind. The bridge of his nose seemed flattened, and he was said to have suffered from the snuffles. The mouth was regularly formed but the child kept it half open most of the time with his tongue more or less between the lips and in constant motion. The teeth, particularly the four upper and the two lower middle incisors, are notched. This change is, even in the first dentition, attributed to syphilis by Parrot,¹ of Paris, and others, but Mr. J. Hutchinson,² in his remarks to the last International Congress in London, says they are caused by stomatitis, either mercurial or not.

"The way in which the teeth meet is peculiar, both molars coming in contact, while generally only the first molars strike when the jaws are closed naturally; during life the teeth did not project much from the gums. The hair was well developed. When quiet, the child's limbs were extended, the hands and feet being flexed, but the spasm of the muscles was only partial, for at times the child would kick and move on the bed like one that was healthy. The tendo-reflex was present at the knee and

in the abdominal muscles, but absent in the dartos. The physical examination was negative, the ophthalmoscopic was not made. When admitted the child was weaned and put on bread and milk with 3 j. of Mardock's food t.i.d.; he seemed to do well until February 28th, when he had a slight dry cough. The physical examination gave nothing, he lost his appetite, which had been very good before, and died suddenly on March 2d. He had no convulsions or other symptoms. He had never walked or made the slightest effort to say anything.

"The autopsy was made on March 3d, 10 A.M., eleven hours after death. Child fairly nourished; well marked rigor mortis. Lungs were congested in the posterior part of the upper and lower lobes; toward the central portion were regions that were rather harder than the rest of the lung substance, and seemed to be commencing catarrhal pneumonia. Heart, liver, spleen, kidneys, intestines, normal.

"Head, as has already been said, was not enlarged, the open fontanel being the only abnormality. When the calvarium was opened a gush of light yellow fluid followed, and what could be collected measured 350 grammes (11½ ounces); quite a little was lost. Before the brain was removed the hemispheres were seen to collapse. The meninges were congested and the convolutions flattened. On section the brain-substance was rather pale and the gray seemed to be normal, while the white substance was decreased, due to the expansion and pressure of the fluid in the lateral ventricles. The thickness of the cortical substance varied between 1 to 1.50 ctm. The ventricles were evenly dilated, their lining membrane very much thickened; the third ventricle was dilated and the various canals leading in and out of it were much dilated, viz., the two foramina of Monro, the aqueduct of Sylvius, and the iter ad infundibulum, and when the spinal cord was removed the fluid was found increased.

"On examination of the base of the brain I found the blood-vessels normal and all the cranial nerves seemed of normal size and consistence except the optic nerves, which were smaller and harder than normal and when the eyes were removed the disk was found to be 1 mm. in diameter and very white, the other structures of the eye were normal.

"The bones of the skull showed nothing of note that has not been mentioned. The orbital plates of the frontal bone are seen to be depressed and the opening of the orbit is increased in the perpendicular diameter, the base of the skull shows the basilar portion of the occipital bone. Internally the skull shows the marks of the convolutions and the arteries, in some places being quite thin; the ossification was normal here as well as in the long bones."

ENLARGED THYMUS GLAND.

DR. LIVINGSTON also presented a thymus gland which was removed from the body of a child one year five months and fourteen days old, that died March 26, 1883.

The mother stated that the child had had "fits" for some time, but had always come out of them on being patted upon the back. The nurse said the child had convulsions when looked at by anybody. On the day before death slight stridor was noticed in the respiration. The child died in one of the "fits."

At the autopsy the body was well nourished; rigor mortis fairly marked. The thymus gland was enlarged equally in all directions, hard to the touch, and weighed twenty-five grammes. (For comparison the thymus from the body of another child, one year and six months of age, and weighing three grammes, was presented.) The lungs were intensely congested and there was considerable bronchitis. The larynx and trachea were congested, but contained no false membrane. The heart, liver, and spleen were normal. The kidneys were intensely congested. The peritoneal cavity contained a small quantity of reddish serum, probably post-mortem.

Dr. Livingston thought that death was caused by press-

¹ Trans. International Congress, London, 1881, vol. iv., p. 35.

² Loc. cit., p. 146.

ure of the enlarged thymus upon the organs within the mediastinum.

DR. J. C. PETERS said that twenty years ago cases of enlarged thymus gland, asthma, and sudden death were reported very frequently. Of late years only a few cases have been reported. Either they had been overlooked or did not occur so frequently as formerly.

DR. GARRISH thought that serrated edges of the teeth occurred in scrofulous subjects, and therefore did not necessarily indicate the presence of syphilis.

EXSECTION OF RIBS FOR EMPYEMA—NEW FORMATION OF BONE.

DR. GERSTER presented a specimen illustrating the new formation of bone after exsection. A boy, five years of age, came to the German Dispensary in the beginning of June, 1882, with empyema of four weeks' duration. The left side of the thorax was filled with purulent fluid, as ascertained by puncture, and was attended by the ordinary symptoms of purulent pleurisy. An incision was made, a drainage-tube was placed in the cavity, and, after the ordinary methods, the cavity was washed out with a weak solution of carbolic acid. The operation was performed on June 24th, and the incision was made in the sixth intercostal space. A few days afterward it was found that the opening was not sufficient to allow of complete drainage, and therefore retention of pus took place, and it was necessary to resort to further measures to secure efficient drainage. The patient then came under Dr. Adler's care at the German Hospital, who performed exsection of the sixth and seventh ribs on June 29, 1882. The patient was dismissed cured on October 29th of the same year. In the beginning of January of this year the boy presented himself again to Dr. Gerster at the dispensary, and it was found that he had grown considerably, that he looked healthy, that the lung had expanded, and the thorax presented its normal appearance. At the place of the former excision, however, a fistulous opening had from time to time showed itself, closed, discharged a little, then closed, then opened and discharged again, and so on. On examination, Dr. Gerster found roughening of the bone, surrounded by a cavity which was filled with unhealthy granulations, which were scraped away with a scoop and the cavity washed out with an eight per cent. solution of chloride of zinc. The cavity, however, did not exhibit the least tendency to close, although it could not contain more than two or three drachms of fluid, and did not communicate with the pleural cavity. He concluded he had to deal with that condition of affairs which sometimes occurs in scrofulous patients where ulceration of the surface of the bone takes place, from which unhealthy granulations spring up without tendency to bone formation or cicatrization. On March 21, 1883, he cut down upon the rib in that locality, and ascertained that the ribs from which the exsection had been made had grown together, that there was a circular opening one-third of an inch in diameter, and corresponding to the site of the drainage-tube, in this newly formed bone, and that behind this there was a little cavity filled with unhealthy granulations. The portion of newly formed bone was exsected, and the wound has closed.

TUBERCULOSIS AND HYDROTHORAX IN A FEMALE RHINOCEROS.

DR. LAUTARD presented specimens with the following history:

"'Mingo' a female rhinoceros, about sixteen years of age, weighing about five thousand pounds, had been for the last thirteen years one of the attractions of Mr. P. T. Barnum's show. Ever since she joined the show she had enjoyed apparently good health, and at the time of her arrival in New York on the morning of last Wednesday, seemed to be as well as usual. She was on the evening of that day fed as usual, and when on Thursday morning her cage was opened, she was found dead, lying in her

natural position, and showing that she had died without a struggle. Her cadaver was brought to the American Veterinary College, when a post-mortem examination was made.

"An incision was made in the median line of the body from the chest to the pubes, and the skin, more than an inch thick, was dissected from the body. The abdominal cavity being open and the contents removed, the following principal lesions were found: Near the stomach and between the cardiac and pyloric opening of that organ, was found a large, nodulated tumor, resting upon the small curvature of the stomach, tuberculous in character, and filling the entire space left between the two openings of that curvature. Spleen and the liver presented several nodulated tuberculous deposits much smaller than the first one. Near the quadrifurcation of abdominal aorta a number of tuberculous deposits were also found. The uterus is mammillated here and there on the body and the horns with tuberculous masses of the size of a walnut, situated in the cellular tissue between the muscular and mucous coat.

"All the organs of that cavity are healthy—the stomach, the intestines, the kidneys, the suprarenal capsule—with the exception of the small deposits already alluded to in the liver and spleen.

"On opening the thoracic cavity it was found to contain twenty-eight gallons of clear serous fluid, which had crowded the lungs into the upper portion of the chest, and the anterior lobes of both lungs were adherent to the thoracic walls by strong fibrous bands. The pleura presented a number of thickened spots containing tubercular deposits. The mediastinum was filled with tuberculous masses, varying in size from that of a pea to that of a child's head. The lungs were dark, of a bluish color, slightly emphysematous at their lower border, and with their surfaces filled with miliary tubercles, very heavy and dense. Heart has both cavities empty and presented tuberculous granules on the tricuspid and semilunar valves. At the base of the heart, around the aorta and pulmonary artery, was found a large mass of tubercles. The pericardium is adherent to the pleura and to the lungs by fibrous bands, but is otherwise healthy. The pericardiac and cardiac lymphatic ganglions are enormously enlarged and indurated. On section they presented a circular wall of dense fibrous tissue, sending off shoots into the centre of the mass, and interlacing each other formed a kind of reticulum or stroma, with a dark greenish aspect in the meshes, containing tubercular deposits of various sizes. On the superior face of the sternum three large tubercles were found attached, and the axillary glands of both sides were very much enlarged, dense, of whitish color. The pectoral, prepectoral, and lymphatic glands of the neck were also much enlarged, indurated, and tuberculous in their character.

"Both of these affections were evidently of old standing, and readily accounted for the sudden death of the animal."

DR. JOHN A. WYETH presented specimens as follows:

FRAGMENTS OF BONE REMOVED FROM THE SKULL BY TREPHINING.

The patient, a man thirty-two years old, came to the Polyclinic six weeks ago. He had been struck on the head with a hammer. A portion of the frontal and parietal bones were driven in. The depression was about one-fourth of an inch. Operation one week after the injury. A large blood-clot was found lying upon the dura mater. A square inch of bone was entirely removed. All the dangerous symptoms disappeared and the patient is fully recovered.

ORIGIN OF THE CALCANEAN ARTERIES.

Two specimens of arteries, showing the derivation of the *calcaneous* branches from the external *plantar*. The necessity of a thorough knowledge of this fact was insisted upon in order to obtain good results from Syme's amputation.

Professor Stephen Smith, who had made an analysis of all amputations, had concluded that re-amputation was more frequently necessary in Syme's than in any other, and that the sloughing was principally confined to the inner flap.

The incision should be made from the anterior portion of the malleoli, directly across the sole, in the axis of the leg when the foot was held at a right angle to the leg. Dr. Wyeth demonstrated, in 1876, in an essay embodying eighty-seven dissections of the tibio-tarsal region, that this method of operating was the only one based upon a thorough understanding of the anatomy of the parts involved. Mr. Erichsen and others advise an incision well back over the heel, on account of redundancy of flap from an incision farther to the front. But a redundancy is better than a re-amputation. Mr. Syme practised the long flap. Mr. Savory, in the *Lancet* for February 3, 1883, advocates the long flap, but neglects to say that his advocacy is based upon a study of the arterial distribution from the calcaneous branches of the external *plantar* (not posterior tibial) to the posterior flap. From the standpoint of practical surgery I wish to reiterate what was said in the Prize Essay of the Bellevue Alumni Association in 1876, that the line of incision, which is carried obliquely backward over the heel, divides the posterior tibial so near its bifurcation that the supply of blood to the heel is insufficient, while the incision well forward (as above described) divides the internal and external plantar arteries well beyond the bifurcation of the tibial and leaves the calcaneous branches of the external plantar uninjured.

ABNORMALITIES OF THE CAROTIDS.

The *arch of the aorta* from a man in which the left *common carotid* artery was absent, the *external* of that side arising from the *aorta* in the usual site of the *common* trunk. The skull of this subject had no carotid canal on the left side. It was presented to the Wood Museum of Bellevue Hospital. It is the second one known to me, the other being mentioned by Hyrtl. Dr. Eugene Peugnet had reported a case of absence of the *common carotid*.

AN INTERNAL CAROTID ARTERY, FROM WHICH THE ASCENDING PHARYNGEAL ORIGINATED, ONE INCH ABOVE THE BIFURCATION OF THE COMMON TRUNK.

It is stated, generally, in the anatomies, that no branches are derived from the cervical portion of the *internal carotid*. Dr. Wyeth found the *ascending pharyngeal* derived from this vessel in seven of one hundred and twenty cases examined.

Twelve specimens of the *common internal* and *external carotid* arteries, in which the distance from the origin of the *superior thyroid* and bifurcation of the *primitive carotid* to the origin of the *lingual*, varied from one half to three-fourths of an inch. The average distance between these two points, he found in an analysis of 121 cases, was $\frac{5.7}{100}$ of an inch.

These specimens went to prove that the application of a ligature to the *external carotid* artery at this point was a safe and justifiable operation. Nevertheless, in performing this operation, it was always safer to examine if any branch was derived within the immediate vicinity of the ligature. If found, it should be separately secured, as a safeguard against secondary hemorrhage.

A specimen in which the *common carotid* trifurcated into the *internal*, *external*, and a single large trunk, which afterward divided into the *superior thyroid*, *lingual*, and *facial*.

This anomaly occurred twice in 121 cases examined carefully. The cases are reported in the Prize Essays of the American Medical Association for 1878.

A specimen showing a common origin for the *facial* and *lingual* arteries from the *external carotid*. I found this condition to exist in 31 cases out of 121.

Three cases showing an exaggerated type of the

normal trumpet-like expansion of the origin of the *internal carotid*.

The explanation he offered for this almost constant dilatation was, that the column of blood projected into the common trunk divided about equally into the two principal branches when it reached the septum of bifurcation. The pressure upon the *external carotid* was relieved by reason of the large number of branches given off by it, while the *internal carotid*, having no such means of relief, expanded under the pressure.

(To be continued.)

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE NEW MEDICAL BILL—HOSPITAL ACCOMMODATION IN LONDON AND ITS ABUSES—MEDICAL FEES.

LONDON, March 31, 1883.

THE new medical bill continues a prominent subject of interest. It is believed that some of the corporations will oppose it, particularly the College of Surgeons, as its diploma of membership will probably die out in the event of the bill becoming law. One objection justly urged against the new bill is, that although it provides for a uniform *final* examination in medicine, surgery, and midwifery, it offers no guarantee that the examinations in the primary subjects of study shall be of equal and sufficient security.

The subject of hospital accommodation in London is again receiving attention. On the one hand, it appears that some districts are insufficiently provided, notably the north of London; on the other hand, there is no doubt that the existing hospital accommodation is greatly abused. This remark applies chiefly to the out-patient departments. There is no doubt that many—it might almost be said most—of the out-patients could afford to pay *something* for the advice and medicine received. In many cases well-to-do middle class people, and even the upper classes, do not disdain to receive gratuitous advice and medicine. In some instances, no doubt, the motive is to avoid expense, but in others such patients attend public institutions under the belief that they will receive better advice than from their family attendant, and they are either unable or unwilling to pay the fee of a hospital physician and consult him as private patients. On one occasion a banker's wife went to an hospital to see a celebrated specialist, and leaving her carriage at the corner, presented herself among the patients attired in her lady's maid's clothes. She was, however, recognized by another member of the staff who happened to be present, and unkindly informed his colleague, so that on a subsequent visit the specialist refused to prescribe for a lady of her position within the hospital walls, and gave her a short lecture on the use and abuse of charitable institutions.

I have known though of a wealthy man attending as a hospital patient in order to "take a taste" of a physician before consulting him privately. This gentleman betook himself for this purpose to a large institution in London which shall be nameless. He entered the physician's consulting-room along with several other patients. One of these approached the great man, and, amongst other symptoms, mentioned his inability to keep awake, and said he could always go to sleep at any time. He was always falling asleep, he said. "Very well," said the physician, "then lie down on that bench and go to sleep." The patient lay down as bid. Several patients were seen and dismissed. The physician then bethought himself of the drowsy one, and, turning toward him, said loudly, "Hallo there, are you asleep?" "No, sir," timidly replied the patient. "Well, go to sleep at once then," responded the doctor. In a few minutes the doc-

tor again demanded if he were asleep, and finding he was not, said "How dare you tell me such a lie as to say you could go to sleep any time?" and scolded and dismissed him. The gentleman *did not* consult that physician, who, I beg emphatically to say, is not a fair specimen of London medical behavior.

Your readers may care to know how our scale of fees runs. General practitioners charge from half a crown to seven shillings a visit, and this charge includes the medicine supplied. Consulting practitioners, whether physicians or surgeons, charge a guinea per consultation. For the first interview it has of late years become customary with many to charge two guineas. For visits, consulting practitioners charge by distance. For short distances a guinea a mile is charged, with a minimum charge of two guineas. For long distances, one-third of a guinea is charged per mile for the double journey; *i.e.*, sixty guineas would be charged for a journey of ninety miles and back. Though these are the accepted fees, it will readily be understood that they are subject to variations. Thus many young physicians are glad to take a guinea for two or even three consultations, and even established hospital physicians and surgeons will sometimes see a patient of limited means an extra time or so without extra charge. Similarly, it is only the busiest men who exact the outside charge for visits at long distances.

MEDICAL EDUCATION IN CHICAGO.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of April 7th is a description of a "Class Quiz on Anatomy in a recognized Medical College in Chicago," which I think should not pass without notice. The article has no signature, and the name of the medical college in which this wonderful quiz took place is not given. If this narrative is anything but a grotesque exaggeration, the class spoken of must have been made up of the champion ignoramuses of America, and it is unjust to other colleges not to specify the one alluded to. A reader not familiar with the schools and laws of Illinois would be likely to suppose that this occurred in a school which is recognized by the profession. Our State Board of Health recognizes all the schools here; but not many who read *THE RECORD* do. We have the Rush Medical College, the Chicago Medical College, the Woman's Medical College, and the College of Physicians and Surgeons, which we recognize; but the others are Homoeopathic and Eclectic, and would not be classed with those named. The scene described could not have been in any of those four schools. None of these have mixed classes, and therefore no "embryo male and female doctors to throw orange-peel before the lecturer began to ask about the abdominal aorta." *THE RECORD* has before said, in substance, that "entrance examinations are unknown in Chicago." This is an error. The Chicago Medical College and the Woman's Medical College established the rule of requiring a good English education as a condition for matriculation in 1875, and perhaps may claim the rank of pioneers in this movement.

The College of Physicians and Surgeons adopted this rule on its first organization in 1882. I have reason to believe that it has been fairly applied by these institutions. I suppose that all medical schools in the State will feel compelled to require this in future; if our State Board of Health adheres to its rule, recently adopted, of not recognizing schools that do not, I think your correspondent is warranted in doubting that the medical practice act of Illinois excludes ignorant quacks from the State. That it does has been claimed, and the claim has been generally admitted. It may be said for this act that it is an effort in the right direction; but if it has driven any quacks from Illinois, I am not aware of it. There are, and always have been plenty of them practis-

ing in Chicago. Some may have been *frightened* away, but I do not think any have been *driven* away. A person has long practised medicine in Chicago under an alias. The Board revoked his certificate several years since, but he has never suspended his practice. A doctor's sign has been on one of the principal streets of this city many years. Several years since his well-advertised name brought him a patient who lost her life in an attempted abortion. An investigation revealed the melancholy fact that the doctor had been a good while dead, but another had personated him, and the infamous business went on without interruption, and the old name still stands at the entrance to invite the unwary across the threshold. I have long been an attentive observer of the condition of the profession in Illinois, and I do not think that our legislation has greatly advanced its interests. The profession has accomplished much through its own organizations by carefully registering its recognized members, and by a persistent demand that medical colleges shall give more thorough instruction to students and exact a higher grade of attainments for graduation. "T is true 't is pity, and pity 't is 't is true," that the medical schools of Chicago confer about five hundred diplomas annually, and that the ease with which they are obtained nearly robs the parchment of its value; yet I doubt if our regular schools distribute their diplomas with a more liberal hand than do those of New York.

E. INGALS, M.D.

CHICAGO, April 10, 1883.

CATHETERIZING THE FEMALE URETER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the *New York Medical Journal*, February 17th, there appeared an interesting report of the extirpation, by Dr. W. M. Polk, of a misplaced kidney. The patient, a girl of nineteen, died eleven days later of uremia, and the autopsy revealed the congenital absence of the other kidney, the excised organ having therefore been the patient's only kidney. After alluding to other cases in which the same operation has been followed by the same result from the same singular cause, Dr. Polk discusses the various possible means for detecting the absence or disease of one kidney before operations upon the other. No mention is made, however, of Pawlik's method for catheterizing the ureter in females—an easy and generally practicable proceeding, which involves no preparation of nor danger to the patient.

As originally demonstrated to the *Versammlung deutscher Naturforscher*, at Salzburg, in 1881, the method was this: The patient is placed in the knee-elbow position, the posterior vaginal wall retracted by means of a Sims speculum; the position of the trigonum vesicæ is recognized by the conformation of the vaginal wall. An elastic bougie (or small catheter) is introduced into the bladder and its point is directed, by inspection and palpation of the vagina, into the orifice of the ureter. Dr. Pawlik subsequently acquired such dexterity that inspection of the vagina (and the use of the speculum) became unnecessary; the finger in the vagina sufficed to guide the bougie. Pawlik has thus repeatedly introduced bougies into the ureters in patients of Billroth as preparation for the vaginal extirpation of the uterus. He informed me last July, that he had thus sounded some thirty patients, and had failed but once, in a case of pronounced prolapsus uteri. The writer is convinced by experience that the proceeding is practicable on the cadaver, at least, though demanding patience and practice.

A sketch of Pawlik's method was communicated to the London Congress, and the doctor intended to publish it in detail with illustrative plates; but so far as I can learn, the article has not yet appeared.

W. T. BELFIELD, M.D.

71 DEARBORN STREET, CHICAGO, ILL.

THE HOLMES DINNER.

THE complimentary dinner to Dr. Oliver Wendell Holmes was given, as announced, at Delmonico's, April 12th. About two hundred and twenty-five guests were present. Almost all of them were medical men, there being representatives from Boston, Springfield, Utica, Albany, Syracuse, Washington, and Philadelphia. Among the laymen present were, Mr. Horace White, John Habberton, Noah Brooks, Bishop Clarke, Hon. Wm. M. Evarts, and Mr. George Wm. Curtis. The guests were seated at five long tables, completely filling the hall. On a raised dais, sat Dr. Fordyce Barker, who presided, at his right Dr. Oliver Wendell Holmes, at his left Right Rev. T. M. Clarke, of Rhode Island. Among others seated on the dais were Drs. Wm. Pepper and S. Weir Mitchell, of Philadelphia, Drs. A. C. Post, J. T. Metcalfe, T. A. Emmet, J. C. Dalton, S. O. Vanderpoel, and I. E. Taylor.

Dr. Barker, in calling the assembly to order, made some happy introductory remarks introducing the guest of the evening. These were supplemented by a poem from Dr. A. H. Smith, which was received with much laughter and applause.

The following is the poem :

You've heard of the deacon's one-hoss shay
Which, finished in Boston the self-same day
That the City of Lisbon went to pot,
Did a century's service, and then was not.
But the record's at fault which says that it bust
Into simply a heap of amorphous dust;
For after the wreck of that wonderful tub,
Out of the ruins they saved a hub;
And the hub has since stood for Boston town,
Hub of the Universe—note that down.
But an orderly hub, as all will own,
Must have something central to turn upon,
And, rubber-cushioned, and true, and bright,
We have the axle here to-night.
Thrice welcome, then, to our festal board
The doctor poet, so doubly stored
With science as well as with native wit;
Poeta nascitur, you know, *non fit*.
Skilled to dissect with knife or pen,
His subjects dead or living men;
With thoughts sublime on every page
To swell the veins with virtuous rage.
Or with a syringe to inject them
With sublimate to disinfect them;
To show with demonstrator's art
The complex chambers of the heart,
Or armed with a diviner skill
To make it pulsate at his will;
With generous verse to celebrate
The loaves and fishes of some giver,
And then proceed to demonstrate
The lobes and fissures of the liver;
To soothe the pulses of the brain
With poetry's enchanting strain,
Or to describe to class uproarious
Pes hippocampi accessorius;
To nerve with fervor of appeal
The sluggish muscles into steel,
Or, pulling their attachment, show
Whence they arise and where they go;
To fire the eye by wit consummate,
Or draw the aqueous humor from it;
In times of peril give the tone
To public feeling called backbone.
Or to discuss that question solemn
The muscles of the spinal column.
And now I close my artless ditty
As per agreement with committee,
And making place for those more able,
I leave the subject on the table.

Yet one word more. I've had my pride
As *medicus* most sorely tried.
When Englishmen, who sometimes show
Of things American, you know,
An ignorance that is melancholy;
As Dr. Holmes is very jolly,
Assume that he must therefore be
A Doctor of Divinity.
So to avoid all chance of wrong,
To medicine, or church, or song;
Let Doctor Holmes discarded be
For Oliver Wendell Holmes, M.D.

And now, for I really must come to an end,
May the fate of the chaise be the fate of our friend.
May he never break down, and never wear out,
But a century old, or thereabout;
Not feeling the weight of years as they fly,
Simply stop living when ready to die.

Dr. H. D. Noyes was then announced as the toast-master; his reading of the subject of the first toast, "Our Guest," was the signal for a vigorous outburst of enthusiasm, all rising to their feet and following the quaffing of their wine by three hearty cheers.

Dr. Holmes then read his poem. He was listened to with the most enjoyable attention. No doubt many were surprised at the freshness and vigor of the speaker's presence, his clear voice, and sympathetic elocution. There was no trace of old age in manner or matter.

The poem has been so extensively printed in the daily press throughout the country that we present only a fragment of it, but sufficient to show the power and pathos of its author:

Have I deserved your kindness? Nay, my friends,
While the fair banquet its illusion lends
Let me believe it, though the blood may rush
And to my cheek recall the maiden blush
That o'er it flamed with momentary blaze
When first I heard the honeyed words of praise.
Let me believe it while the roses wear
Their bloom unwithering in the heated air;
Too soon, too soon, their glowing leaves must fall,
The laughing echoes leave the silent hall,
Joy drop his garland, turn his empty cup,
And weary Labor take his burden up—
How weighs that burden they can tell alone
Whose dial marks no moment as their own.

Am I your creditor? Too well I know
How Friendship pays the debt it does not owe,
Shapes a poor semblance fondly to its mind,
Adds all the virtues that it fails to find,
Adorns with graces to its heart's content,
Borrows from love what nature never lent,
Till what with halo, jewels, gilding, paint,
The veriest sinner deems himself a saint.
Thus while you pay these honors as my due
I owe my value's larger part to you.
And in the tribute of the hour I see
Not what I am, but what I ought to be.

Brothers in art, who live for others' needs
In duty's bondage, me:cy's gracious deeds,
Of all who toil beneath the circling sun
Whose evening rest than yours more fairly won?
Though many a cloud your struggling morn obscures
What sunset brings a brighter sky than yours?

I, who your labors for a while have shared,
New tasks have sought, with new companions fared,
For Nature's servant far too often seen
A loiterer by the waves of Hippocrene;
Yet round the earlier friendship twines the new,
My footsteps wander, but my heart is true
Nor e'er forgets the living or the dead
Who trod with me the paths where science led.

How can I tell you, O my loving friends,
What light, what warmth your joyous welcome lends
To life's late hour? Alas! my song is sung,
Its fading accents falter on my tongue.
Sweet friends, if shrinking in the banquet's blaze,
Your blushing guest must face the breath of praise,
Speak not too well of one who scarce will know
Himself transfigured in its roseate glow;
Say kindly of him what is, chiefly, true,
Remembering always he belongs to you;
Deal with him as a truant, if you will,
But claim him, keep him, call him brother still!

As Dr. Holmes read the last line he sank back into his seat, and a loud cheer burst from the listeners, which lasted for at least a minute. Several ladies had stood in the gallery overlooking the room, and they waved their handkerchiefs and applauded as heartily as the men did. Suddenly Mr. Evarts jumped to his feet, swinging his handkerchief in the air, and in an instant every man in the room was standing, shouting and cheering and waving napkins and handkerchiefs. It was a scene of enthusiasm seldom witnessed even in Delmonico's, and Dr. Holmes bowed his thanks with a face in which smiles and tears struggled visibly for the mastery.

The speeches that followed were exceptionally good. Bishop Clarke, of Rhode Island, responded to the toast "The Clergy." He said, among other things, "When the name of Dr. Holmes is spoken, we do not think of bones and ligatures and lesions. It is difficult to conceive of him as ever administering to a poor man anything that it

was hard for him to take. If he had not been great in so many other ways we might consent to think and speak of him as the great doctor. How much we learn from him, and how much we are impressed by his glowing words! As we read we weep, and sigh by turns, but the glad song of the bird is always heard above the sad moaning of the sea. Whatever chord he touches, the answer comes back from the soul, prompt and clear. But I am diverging from my subject, which is the clergy. Now, we clergymen are proud of Dr. Holmes, because we consider him as one of us. If he had never had a father he would never have been, and his father was a clergyman, so that he is really one of our production. We are very grateful to the father for producing such a son. Long may it be before the sun of his life sets."

Mr. Evarts responded to the toast, "The Bar." He began by complimenting the doctors. "It is much pleasanter," he said, "to be asked to meet three hundred doctors in this way than it is to ask one to meet you. An old German book on medicine lays down the sweeping proposition that all diseases and all accidents requiring surgical treatment are caused in order that the skilful and learned in the profession of medicine may be educated by means of them. I don't know, after all, but there is a good deal of feeling in the three learned professions that this is a true view of human affairs. The estate, the body, and the mind make up, do they not, all that is visible, all that is interesting, all that is important in human affairs? The lawyer takes charge of the estate, the clergyman is the curer of the souls, and the doctor is the curer of the bodies. As the sheep are for the shepherd, so those taken care of are for those who take care of them. You medical men have one striking advantage over the rest of us, for though, alas, everybody has not an estate, and everybody has not a mind, yet everybody has a body. We are all bound to be in at the death, and although it is a cheerless moment, yet to us there are assuaging circumstances. In contrasting our relations I should say that Bishop Clarke and his fellow-laborers are sent out as sheep among wolves; you and I are sent out as wolves among the sheep." Dr. Holmes, Mr. Evarts said, "had the advantage of being born and living near to Boston, a place that no one can live early in life without feeling that he has a great advantage over his fellows, and no one who first learns it later in life fails to be grateful that he has seen it before he dies. Now fame was nothing to Dr. Holmes in influencing him to pay us a visit. The only curiosity that he had in the matter was to see how a Boston fame would sound echoed from New York. I never could understand how the Boston people were able to put up so long with Dr. Holmes, who, while he furnished a reputation to Boston, took also the principal part of the reputation of Boston to himself. Now," said Mr. Evarts in conclusion, "as we are all professional men here, and as the rest of the world is shut out, and there is no possibility of anybody knowing what we say or do here, is it not fair for us, does not our character for truth require us, to admit that we are really the saviors and protectors of society? Why should we strive to hide this even from ourselves? Let us animate ourselves to a more vigorous pursuit of our several interests, as sheep and wolves! Let us understand that the laborer is worthy of his hire, and that those who are unwilling to be aided by professional skill and advice in parting with their property and their lives are unworthy of serious consideration."

"The Medical Profession" was responded to by Dr. T. Gaillard Thomas. He said that everybody knew that nothing was so difficult for a medical practitioner as the making of an impromptu speech. He felt embarrassed when asked to present his speech between the speeches of the two eloquent gentlemen who had preceded him and those who were to follow. But he felt that a person must indeed be barren in thought and entirely bereft of speech if he could not express in some way his appreciation of the sweet and noble qualities of the honored

guest of the evening. Dr. Holmes was not only an honor to the medical profession, he was an honor and a blessing to mankind. He concluded with an eloquent tribute to the character and genius of Dr. Holmes.

George William Curtis responded to the toast of "Literature." He said that medicine, the church, and the law had spoken praise of the honored guest. As the church was supposed to dispose satisfactorily of a man's mind, the law most summarily of his estate, and medicine inevitably of his body, what was there left for literature to do but to claim the man in his entirety. One profession had cried "All hail, Macbeth!" Another, "All hail, thane of Glamis!" A third, "All hail, thane of Cawdor," and it remained for literature to cry, "Hail, King that shall be!" It was appropriate that literature should assert its claim upon Dr. Holmes, for in literature he had attained his greatest reputation and honors. It was also appropriate that the literature of New York should extend the hand of fellowship to the eminent literary son of Boston. The speaker referred to the literary work done by New York men, Cooper, Halleck, Irving, and Drake. His speech was a wonderful specimen of finished oratory, and excited great applause.

Mr. Whitelaw Reid responded to the toast "The Press." In concluding he said: "Your honored guest, Mr. Chairman, must have seemed to every one here the youngest man at your table to-night. Yet we know, and perhaps may venture to say, that save for the ever youthful spirit, he is no longer young. The man who has written thirty-two successive annual poems for the class of 1829 must not be surprised that all the world knows by heart—if not his precise age—at least how long he has been out of college. It is one of the pleasantest things connected with his formal relinquishment of some of the burdens he has been bearing that he has the right, in this mellow Indian Summer of his fruitful life, to know that his fame is still a growing one. The very flash and glitter of his wit have sometimes blinded men's eyes to the rich and generous qualities that lay beneath it. Lowell painted him as

"A Leyden-jar, always full-charged, from which flit
The electrical tingles of hit after hit."

This tribute from your profession, Mr. Chairman, has served to recall to us how many more are his titles to renown; how wide has been the field of his work and how rich the harvest he has gleaned. And it gives us the welcome opportunity to show that New York prizes him no less than Boston; and is glad to thank him alike for the pleasure he has for so many years given us all personally; for the example of his life, for the service he has rendered our literature, and the honor he has done our country."

On the conclusion of Mr. Reid's speech, Dr. Barker referred to a number of physicians who had sent letters of regret, and then called for a bumper to absent friends. It was drunk standing and the company sang "Auld Lang Syne" right heartily as a response, and then separated.

BRAINS OF GREAT MEN.—General Skobelof, the hero of Plevna, after death was subjected to a rigorous autopsy. The circumference of his head was 57 centimetres; of the skull, 54; antero-posterior diameter, 18 centimetres; transverse, 14. The brain weighed 1,457 grammes. The brain of Gambetta is deposited in the laboratory of the School of Higher Studies, and will be described by M. Mathias Duval of the Society of Mutual Autopsy, to which M. Gambetta also belonged.

THE HEALTH RECORD OF NEW ORLEANS from 1863 to 1882, as given by the Louisiana State Board of Health, shows a remarkable and steady improvement. In 1863 the mortality was 41.35 per 1,000; in 1873 it was 37.73; in 1882 it was 26.45.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 7, 1883, to April 14, 1883.

ALEXANDER, CHARLES T., Major and Surgeon. To be relieved from duty at the U. S. Military Academy, West Point, New York, August 28, 1883. S. O. 82, par. 6, A. G. O., April 10, 1883.

BARTHOLF, JOHN H., Captain and Assistant Surgeon. The extension of leave of absence for twenty-three days by S. O. 37, C. S. Department of the Columbia, further extended one month. S. O. 31, par. 1, Military Division of the Pacific, April 3, 1883.

GIBSON, R. J., Captain and Assistant Surgeon. Relieved from duty at cantonment on the Uncompahgre, Colorado, and assigned to duty at Fort Hays, Kansas. S. O. 73, par. 1, Department of the Missouri, April 7, 1883.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 17, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

Pneumonia still figures largely among the causes of death, the number for the week ending April 14th being 131 out of 721, the total number of deaths reported.

A SIMPLE AND INGENIOUS INSTRUMENT FOR REMOVING FOREIGN BODIES FROM THE EAR.—Dr. Louis B. Couch, of Nyack, N. Y., sends us the description of a little instrument which any jeweller can make, and which, he says, is very useful and efficient in removing foreign bodies from the ear. The description is as follows:

I have been interested in the late discussion going on in your journal with reference to the best methods for the removal of foreign bodies such as corn, beans, etc., from the auditory canal or nares, and herewith transmit my mite to the general fund of information.

Take a piece of eight-sided brass wire, or round wire with roughened surface, and drill into either end a small hole a quarter of an inch deep. Into one end bronze or solder a small twist drill one thirty-second of an inch in diameter, and into the other a nice sharply cut screw (such screws may be obtained of any jeweller) of about one twenty-fifth of an inch in diameter. When this is done, you are ready for your smart boy with more beans in his head than brains.

Suppose the bean is at the bottom of the auditory canal, enlarged and surrounded by inflamed swollen tissues, a small portion only being visible.

Introduce the speculum, and carefully with light pressure drill into the presenting portion of the corn or bean to the depth of about one-quarter of an inch, and clear

off all dust, then reverse the instrument and insert the screw and the bean must come.

I have by actual test inserted my sample instrument into a bean, and sustained with it a weight of twenty-five pounds, as shown by scales; a holding power far in excess of that required for the removal of any such bodies.

Physicians will be surprised at the rapidity with which the drill will perforate the hardest of dry beans and the slight pressure required. Care, however, should be exercised in first entering the drill, that it does not slip.

I confidently recommend this instrument to the profession in all cases for which it is applicable.

WRITTEN AND UNWRITTEN ETHICS.—We venture the statement that of the 75,000 practitioners of medicine of this country, not ten per cent. have ever read the Code of Ethics of the American Medical Association, and that not five per cent. even of the ethically correct in their department toward both the public and their brother practitioners remember enough of it to be of the slightest possible value to them as a guide to conduct. Certain it is that as a guide to the every-day conduct of the physician, it is as if it did not exist. The gentleman does not require it, and he who is not a gentleman can utilize it to cloak his rascality. One of the greatest sticklers for the code whom we know, is notoriously unfair toward his brother practitioners, injuring them by innuendo and robbing them of their patients when he can. Correct medical conduct requires more than can be formulated in words. It requires that rare admixture of regard for others, self-respect, charity, and magnanimity which goes to make up the gentleman. No code can define the constituents of this admixture, and any code which cannot define it is useless, and in many respects injurious. Better than such a code is the unwritten and indefinable law which defines a gentleman. If physicians were absolved from the obligations of gentlemen, and required only not to violate the Code of Ethics of the American Medical Association, the profession of medicine would soon cease to be the honorable calling that it is.—*Medical Age.*

NEW MEDICAL COLLEGES.—Dr. Richard C. Moore, of Omaha, Neb., writes: "The position you have usually taken in reference to new medical colleges being established in cities already occupied or in towns too small to furnish clinical material, I consider correct; but in referring to the Omaha Medical College in the same article in which mention is made of new colleges in Boston, organized under act incorporating *manufacturing companies*, you do an act of injustice to a flourishing and honest institution."

Dr. Moore then describes to us, in a temperate manner (barring a slight exaggeration of his city's population), the advantages which Omaha possesses as a medical centre. There is also, we are told, no medical college equal to that in Omaha, short of St. Louis or Chicago, five hundred miles away. Our correspondent is plainly a sensible and judicious gentleman. We are anxious to do his institution justice. We cannot, however, force ourselves to believe that the lack of medical men in the West is such as to require the establishment of more colleges, even though, like that at Omaha, they require "two full terms of six months each."

THE AFTERBIRTH MISTAKEN FOR INTESTINES AND RETURNED.—A correspondent from the Sandwich Islands sends us the following: "Some of the statements about obstetrics in the Sandwich Islands made in THE RECORD are not quite true, but the following is what took place here: 'An Englishman's donkey had a colt, the first the man had ever seen born. When the after-birth came he thought it was the bowels, and so he and two other white men took a stick and pushed it back. This they did three times, and at last out of pity they shot the donkey. The man said, 'I did not like to see the animal suffer for want of bowels.'"

ADVERTISING IN LAY JOURNALS.—The Irish College of Physicians has followed in the steps of the English College in adopting the following resolution: "That the advertisement of medical books in other than medical publications, and the giving by any of the licentiates, members, and fellows of the college, whether for publication or not, of laudatory certificates of medicinal or other preparations, or medicinal or surgical appliances, is misleading to the public, derogatory to the dignity of the profession, and is censurable by the college."

HEALING THE SICK BY FAITH.—The "Rev. Dr." Monck, "teaching and healing pastor" of the "Apostolic Church of the Divine Gifts," conducted a public exhibition in the Academy of Music, Brooklyn, Sunday evening. Curiosity, belief, and liberal advertising filled the house with people of simple appearance and decorous behavior. The exhibition of "healing" the sick was preceded by a suitable discourse. Then the process of healing began. Little children, men, and women came forward; the doctor announced their disease, spoke his formula, asked how they felt, interpreted their answers to the people, and hurried them aside.

To the above we append the following anecdote: "Have you ever tried the faith cure?" asked a long-haired, fallow-faced stranger, addressing a gentleman who sat behind him in a street-car. "I have," was the answer. "Do you believe in it?" "I do." "May I ask, then, of what you were cured?" "Certainly. I was cured of my faith."

A NEW REMEDY FOR AN OLD DISEASE—HYDRIODIC ACID IN THE TREATMENT OF ACUTE INFLAMMATORY RHEUMATISM.—Dr. James Craig, of Jersey City, N. J., writes us: "Before using the remedy shortly to be spoken of, I was in the habit of prescribing bicarbonate of potassa, which, as a rule, gave relief as soon as the urine was rendered alkaline, which required about a week or ten days, and during that time opiates had to be given to relieve pain and produce sleep. I have also prescribed salicylic acid, but cannot say that I have seen any decided benefit derived from its use. [!] Syrup of hydriodic acid, prepared by Robert W. Gardner, of New York, is the remedy *par excellence* for this painful and troublesome affection. I have used it for the past two and a half years in bronchitis and scrofula, but its effects have been most prompt in acute inflammatory rheumatism, relieving pain in from twelve to forty-eight hours. I have been called to see patients suffering from this affection, and found them with high fever, joints swollen, and suffering terribly, and on the following day have been agreeably surprised at their rapid improvement, finding them in a great measure free from pain, and fever reduced. Some other cases take a longer time, but I have yet to find one that was not in a comfortable condition within forty-eight hours. The dose I prescribe for adults is from two to three teaspoonfuls every two or three hours, in a wine-glass of water, until relieved; afterward I reduce the dose to one teaspoonful, which may be continued for five or six days, at longer intervals. I was first led to the use of this remedy in prescribing for a patient suffering from bronchitis complicated with rheumatism, its effects being most salutary in the relief of both diseases. I should state that under this mode of treatment the heart has been free from complications; the remedy preventing exudation and organization of plastic material. I more frequently use it now in rheumatism than in bronchitis—in fact, I use it in all cases of acute rheumatism, and must say have always been pleased with its results. I have also prescribed it in chronic rheumatism, but with less effect. I hope that other physicians will give it a fair trial, and find it as useful in their hands as it has been in mine."

MENSTRUATION.—In a lecture on the subject of the comparative physiology of menstruation, by Dr. Alfred Wiltshire, of London (*British Medical Journal*), in which he adduces proof of menstruation in various brutes, the following curious statements are quoted: "Velpeau (*Tr.*

Comp. de l'Art des Accouch., t. 1, p. 126) says that in Lapland and Greenland women are not often more regular than every three months, and Gardien (*Tr. d'Accouch. et de Mal. des Femmes*, t. 1, p. 233) pretends that in women in polar countries the menstrual flow takes place only twice or thrice a year."

POWDERED RHUBARB.—Mr. George W. Hayes has made some investigations into the quality of and tests for powdered rhubarb. *New Remedies* says: "Some of the samples examined by Mr. Hayes contained more cathartic acid (the laxative principle) than the standard, and the inference that may be drawn from his investigations of twelve specimens, some of them obtained from thoroughly respectable and conscientious dealers, is that powdered rhubarb may be of value commercially, but is not to be depended on therapeutically. In other words, we may paraphrase a famous *mot* by *Punch* as follows: 'Advice to those about to purchase commercial powdered rhubarb. DON'T!'"

ERGOT IN THE TREATMENT OF CONGESTIVE HEADACHE.—Dr. Charles T. Rogers, of Honolulu, Hawaiian Islands, writes us regarding the above subject, referring to an article by Dr. J. L. Corning in *THE RECORD* of December 23d. Dr. Rogers thinks that the value of ergot in this trouble is not appreciated. He gives it in large doses (ʒj. of fluid extract) and would not be afraid to repeat it within an hour. He combines it generally with a full dose of bromide of potassium (gr. xl. or more). The combination is much more effective than bromide alone. Dr. R. says that he is not at all afraid to use ergot in large doses. He has seen ʒss. given for pulmonary hemorrhage without toxic symptoms following.

OPHTHALMIC APHORISMS.—Dr. J. J. Chisholm, of Baltimore, gave the following aphorisms in a report presented to the Maryland State Medical Society at its last session:

First Aphorism.—Do not blister. In forty-nine applications out of fifty, as I find it used by physicians at large, it is an additional and useless torture to the eye diseases from which the patient is already suffering.

Second Aphorism.—Do not use nitrate of silver. As constantly prescribed by general practitioners, it is not beneficial in one case out of one hundred, and therefore is a very painful infliction to the ninety-nine who would have been so much better off without it.

Third Aphorism.—Do not prescribe sugar of lead. In every case zinc, tannin, or alum is better, and then there is no fear of having insoluble deposits incorporating themselves with the exposed surface of corneal ulcers.

Fourth Aphorism.—Always use weak solutions of the mineral and vegetable astringents in the treatment of eye inflammations which attack the mucous surfaces, and restrict their application to conjunctival diseases exclusively. One grain of alum, sulphate or chloride of zinc, sulphate of copper or nitrate of silver, in an ounce of water, will, in the majority of cases of conjunctival diseases, do much more good and give much less uneasiness than the very painful five and ten grain solutions which are so often injuriously prescribed by physicians.

Fifth Aphorism.—Solution of the sulphate of atropia, from one to four grains to the ounce of rose water, is an essential eye-drop in the treatment of acute iritis, to break up newly formed adhesions. One drop of atropia solution in an inflamed eye is a most valuable means of establishing the diagnosis whether iritic complications exist or not, and should be used in most cases of eye inflammation to find out whether there are any adhesions of the pupil to the lens.

Sixth Aphorism.—Eserine, in solution of one grain to the ounce of water, is the remedy for purely corneal lesions.

Seventh Aphorism.—When physicians are in doubt as to the character of an eye disease, they should seek a consultation from specialists who are more familiar with the eye diseases than general practitioners can possibly be. Such timely aid often saves the patient a lifetime of trouble.

SCARLATINAL NEPHRITIS AND ITS COMPLICATIONS.

By JOHN H. RIPLEY, M.D.,

PROFESSOR OF DISEASES OF CHILDREN IN THE NEW YORK POLYCLINIC.

IN the following paper it is intended to consider some of the more important points of practical interest in the subject of scarlatinal nephritis. The views therein expressed are based on personal clinical observation. Special reference is had to prognosis and the indications for treatment. As it is believed that the great object in the management of the disease should be to give the inflamed kidneys rest by having their work done vicariously, the number of drugs recommended is correspondingly small.

The subjoined case presents many instructive features, and is especially illustrative of the subject under consideration.

W. McG—, four and a half years old, had whooping-cough when two years and a half old, and a year later an attack of measles. From both of these diseases he made perfect recoveries, and had had no other important ailment when the present illness began, September 2, 1881, with fever and vomiting. I was sent for, September 4th, and found him with the earlier symptoms of scarlet fever. There was a small area of red rash over the upper part of the chest and another at the root of the neck behind. The fauces were reddened, the tonsils swollen, and the tongue presented its ordinary raspberry appearance in that disease. The temperature was 103° ; the pulse, 160. The skin was hot and dry, and the patient quite restless. I prescribed a tepid bath and a diaphoretic mixture.

September 5th.—The rash now covered most of the body. Temperature, 102° ; pulse, 140. Patient more comfortable.

September 6th.—About the same. Has vomited twice since yesterday. Temperature, 102.2° . Urine examined with negative results.

September 18th.—10 A.M.: Since the last note the boy has been doing tolerably well, but he has remained peevish and feeble, and the temperature has fluctuated between 100° and 101.5° during the interval. Desquamation has been slight. The fauces have remained congested. The urine has been repeatedly examined, but there has been no evidence of kidney complication until to day. Since midnight last night no urine has been passed, the patient cannot void any now, and there appears to be none in the bladder. The boy has been wakeful and restless since early this morning, and has vomited several times. Pulse, 130; temperature, 101° . Pressure on the kidneys causes some pain, but it is not very decided. Flaxseed-meal poultices containing foxglove leaves are to be applied over the lumbar region, and twenty drops of the U. S. solution of morphine are to be given every two hours until the patient gets quiet and dozy.

September 19th.—Three consecutive doses of the morphine were given, when the boy fell asleep and slept for three hours. The medicine was then continued at intervals of between three and four hours, and quiet thus maintained. He perspired a good deal throughout the day and night, but no urine was voided until this morning (thirty hours) at four o'clock, when he passed about

two drachms which was thick and bloody. He has taken buttermilk, fresh milk with lime-water, beef-juice and water, in dessertspoonful doses and has vomited only three times. He looks very pale and has a dry tongue. Temperature, 101° ; pulse, 130. At times a little delirious. No œdema. Treatment continued. 5 P.M.: After several fruitless trials he succeeded, about an hour ago, in passing a couple of teaspoonfuls of urine of the same appearance as the last. His general condition remains unchanged. Same treatment.

September 20th.—Sixteen hours after the last urine reported above was passed, he voided about an ounce which was of a lighter color than the former; and again, four hours later, two drachms. This last I carefully examined microscopically, after allowing it to stand in a champagne-glass for half an hour. It contained all the varieties of casts common in acute scarlatinal nephritis—hyaline, epithelial, blood, and granular. The multiplicity of forms of these bodies was a matter of especial interest to me. There were large and medium-sized epithelial, and granular, and blood casts; small straight, and long, narrow, curved, and colorless casts; and a number of small, twisted, worm-like, or pig-tail forms. Of the first two forms there was a large number—a dozen or more in a single field ($\times 500$). Besides casts, the urine contained, of clinical importance, a profusion of red and white blood-corpuscles and tubular epithelium. This specimen was not examined for albumen.

September 22d.—Urine a little more free; about four ounces having been passed during the last twenty-four hours. It continues of a dark, smoky color. There is still no dropsy of cavities or tissues. Erysipelas appeared at the left base of the nose last night and now involves the lower half of the organ and a small area of the adjoining cheek. Temperature, 101° ; pulse, 126. Had one severe attack of vomiting in the night, but none since. The amount of nourishment has been increased. The tincture of iron in five-drop doses every three hours is now prescribed for the erysipelas.

September 23d.—The water is still dark and scanty, only six ounces having been passed during the last twenty-four hours. As usual, since the beginning of the kidney trouble, the boy perspires freely, although less so now than during the two preceding days. The erysipelas is fading at the site of the original invasion, but now involves a portion of both cheeks, and these parts are quite red and tender. The tongue is moist at the edges, but still dry in the centre. Emaciation has been rapid. Only one dose of morphine has been given since yesterday, and only one attack of vomiting has occurred in the interval. Pulse, 116; temperature, 99° . The urine presents the same microscopical appearances as at the last examination. About one-third of its volume solidifies with heat and nitric acid.

September 24th.—Patient improving. He has passed a pint of urine since yesterday. He is hungry and retains large quantities of food. The erysipelas is fading.

September 25th.—Still gaining.

September 27th.—The boy has a ravenous appetite. The urine is now about normal in quantity and of a lighter color, but contains yet a large number of casts of all kinds; those from the smaller tubes being the more numerous. Less red blood than at former examination, and more leucocytes. Albumen diminished.

October 6th.—Since the last report the patient has been gaining until yesterday, which was a poor day; he

was unusually feeble, had no appetite, and his face was very pallid. The urine is again dark and scanty and contains an increase of blood and casts.

October 9th.—Better again. More and lighter-colored urine.

October 11th.—Convalescent. The urine still contains a few casts, some red blood globules and leucocytes.

October 13th.—Gaining rapidly in flesh. Urine slightly albuminous and contains a little blood, but no casts.

October 31st.—Urine normal. No sequelæ.

The special interest in the above case pertains to (1) the unusual grouping of symptoms, and (2) the fact that the child recovered notwithstanding the gravity of the kidney lesion, which was indicated by both the anuria and the microscopic appearance of the urine.

Dropsy is one of the earliest and most constant symptoms of scarlatinal nephritis. So well established is this fact that "renal dropsy" and "dropsy after scarlet fever" have often been used by intelligent practitioners and writers as synonymous terms with "scarlatinal nephritis." Thomas¹ recognizes it as one of the initial symptoms, and so does Roberts.² Bartels³ says: "The insufficient excretion of water by the kidneys leads to dropsy—a symptom which is scarcely ever absent in the severer cases of acute parenchymatous nephritis, although very often absent in the milder cases. The opinion expressed by the last-named author quoted is in full accord with my own experience, and hence I consider it noteworthy that this boy had not an observable trace of serum-infiltration during his entire sickness.

In this connection it may not be entirely irrelevant to state that I have observed in a few instances, in children suffering from acute nephritis, symptoms which could most easily be explained by supposing *pulmonary interstitial œdema* to be present. Such children had not excessive anasarca, and the congested face, rapid pulse, and frequent respirations were suggestive of pneumonia. On examination of the lungs, however, a little dull tympanitic percussion would be obtained, a slight bronchial or rude character to the respiration, and, perhaps, a few moist râles would be heard, but nothing indicating either intra-alveolar œdema or pneumonia. If any cough accompanied the other symptoms it was dry and short and infrequent. The temperature varied, but was generally from 100° to 103°. Hertz⁴ recognizes an interstitial œdema of the lungs as sometimes occurring during a chronic nephritis and giving rise to the "so-called *uræmic asthma*." But the manifestations and physical signs of *uræmic asthma*, as I have observed it, are precisely the same as those of *bronchial asthma* produced under other circumstances and by other causes, and besides it will often quickly and entirely disappear after a full dose of morphine or a hydragogue cathartic. Now, to account for *uræmic asthma* by calling it an interstitial pulmonary œdema, we must suppose the calibre of the smaller bronchi to be reduced by the infiltration of their walls at the same time that the alveolar capacity remains uninvaded; for otherwise the symptoms and physical signs would not simulate bronchial asthma. Such a condition would seem very improbable. The cases of supposed interstitial pulmonary œdema which I refer to, lasted several days each, and, although modified at times in the severity of their symptoms, there was no complete intermission during the whole period of attack.

The *low temperature* in this case, when considered in relation to the severity of the onset of the disease, is noteworthy. Gee⁵ states that pyrexia accompanies the onset of renal dropsy and is high in proportion to the severity of the symptoms. This accords with my own observations and is the general rule according to most authorities. In several fatal cases of which I have record, the temperature ranged between 103° and 106.5°. A low tem-

perature, therefore, in otherwise grave cases, may prove to be of prognostic value.

Prolonged anuria, as one of the manifestations of scarlatinal nephritis, justly excites the apprehension of the experienced physician.

Bartels¹ says: "Apart from the individual conditions and complications, the prognosis may be set down as absolutely bad, so far as my own experience goes, in every case (with the exception of cholera nephritis) in which the suppression is complete. In no such case have I ever seen recovery take place."

So, too, Thomas² considers the prognosis unfavorable when there is "great diminution in the secretion of urine, or complete anuria for several days with or without signs of uræmia, and with or without fever." West³ expresses himself still more strongly, as follows: "Of all indications furnished by the urine none is of such constantly evil import as a marked diminution in the quantity of that secretion, especially when such diminution takes place suddenly; and in whatever other respects the state of a patient may differ, complete suppression of urine for a period much exceeding twelve hours almost invariably announces the speedy approach of death." Although the cases of nephritis from scarlet fever that I have observed have, in a large majority of cases, terminated in resolution, still this is the first instance which has fallen under my observation of a child recovering from acute nephritis after a total suppression of the urinary secretion of more than fifteen hours. And if I have found the prolonged suppression of urine in scarlatinal nephritis so uniformly followed by death, anuria occurring during an attack of *diphtheritic nephritis*, even of much shorter duration, has in my experience been equally fatal. I cannot agree with Jacobi ("A Treatise on Diphtheria," pp. 90-91), that nephritis is of such rare occurrence at a very early period in diphtheria, but I believe it is a complication of great danger, both in that disease and in scarlet fever, when occurring thus early.

It is very important in these cases of nephritis not to mistake retention for suppression. Children will sometimes retain their urine in the bladder for many hours when there is no lack of secretion. Should percussion over the bladder leave us in doubt, a catheter can be introduced and the question thus positively answered.

A number of cases of prolonged anuria from acute nephritis have been published, which show how, partly by vicarious excretion and partly by special tolerance of the system to the retained poisons, patients have been enabled to endure this condition for an unusual period before a fatal result ensued, and some have even recovered. Dr. C. Lellman has referred me to a very interesting case of scarlatinal nephritis, reported by Biermer,⁴ in which the suppression of urine lasted at one time five days—fatal. Dr. L. Haupt, of this city, has kindly furnished me with notes of the case of his little nephew, six years old, who, about the beginning of the fourth week after an attack of scarlet fever, began to suffer from nephritis, which caused great anasarca, and, at one time, a total suppression of urine for thirty-six hours. The child ultimately recovered.⁵ Meigs and Pepper mention two cases of prolonged suppression due to scarlatinal nephritis. In the case of a boy between one and two years old there was no discharge of urine for thirty-six hours. In the other case, which occurred in a girl between three and four years old, no urine was passed for five successive days, and there was no accumulation in the bladder. The patient suffered very much and passed nearly the whole time in a semi-comatose state, but could be roused and then showed some intelligence and complained of headache. Vomiting was persistent. She had no convulsions and finally recovered.

I saw, with Dr. L. D. Sproat, a few months ago, a man, thirty years old, who was taken suddenly with fever, in-

⁵ Diseases of Children.

tense headache, pain in the back, and vomiting. From the onset of the disease until the death of the patient from pneumonia, nine days later, only a few ounces of urine were passed, which was bloody and became nearly solid by boiling. At one time during his sickness he passed no urine for three days, and at the end of that period only about an ounce. For forty-eight hours before he died he passed no urine. A catheter was several times introduced, but none found. He had no convulsions, and delirium was not marked until the last day of life, when he gradually lapsed into deep coma. His temperature was about 103° until pneumonia developed, about the seventh day of his illness, when it became more elevated. In this case, as in my own, there was no dropsy. The theory of Harley¹ that "anasarca, in fact, only makes its appearance when not alone both, but the whole of both kidneys are so much affected as to be unable to excrete the urinary products," is disproved by such cases as these. According to Ebstein,² complete anuria from nephrolithiasis may exist and go on to a fatal termination, and yet one kidney remain healthy.³

The quantity of albumen alone furnishes no trustworthy guide for prognosis. In some cases of acute nephritis, as also during acute attacks in old cases, I have seen the urine rendered nearly solid by coagulating its albumen, and yet the patients make good recoveries, whereas some of the very worst cases have had proportionately small amounts of albumen. I have often found it in the urine of diphtheritic patients in considerable quantities when casts were absent and other kidney symptoms mild. As is well known, temporary albuminuria occurs in malarial fever patients, even in cases in which the temperature is comparatively low, but, as a rule, it disappears without causing serious complications. I have had no experience in those rare cases of scarlatinal nephritis associated with various dropsies in which albuminuria is absent. Bartels emphatically states that he has never seen a case of acute parenchymatous nephritis in which the urine was not albuminous, although, in a few cases, he has known the dropsy to precede the albuminuria for a short time. However, Thomas, Niemeyer, Reynolds, Frerichs, Steiner, and others recognize such a form of acute nephritis. Dickinson⁴ reports a single cure which came under his care, with the autopsy.

Philippe, of Berlin, is said to have examined the urine of sixty patients suffering from scarlatinal anasarca, during a certain epidemic, without once finding albumen. In regard to the prognosis of such cases, Niemeyer speaks of it as "a sequel of scarlatina as free from danger as it is inexplicable." Johnson,⁵ however, quotes two cases from Roberts, both of which were fatal. The autopsy on the second case, after five months' illness, showed the kidneys "to be good examples of the smooth white 'Bright's kidney.'"

The number and forms of casts found in the urine are, in my opinion, of great value in determining the prognosis. A small number of straight casts suggests a mild attack. Although a large number pretty uniformly indicates a severe form of the disease in scarlatinal nephritis, it is of still more evil import in diphtheritic nephritis. This arises from the fact, I believe, that when this marked form of nephritis occurs in diphtheria, that disease is in other respects more severe, and the kidney affection occurring, as it often does, during the early stage of the attack, the system has a double poison to withstand.

When all parts of the kidney are represented by casts, as in this case, I believe the gravest apprehension should be felt as to the result. My own observations are limited to five cases. One, a case of diphtheria, elsewhere reported, died (MEDICAL RECORD, 1880). The second,

a young married woman with scarlatinal nephritis, a patient of Dr. Milne, died. The third, a girl six years old, also scarlatinal nephritis, died. The fourth, a girl four years old, nephritis following scarlet fever, died. Dickinson¹ has reported a similar case, with a drawing representing the appearance of the casts, which was also fatal. The fifth, the boy on whose case these remarks are based, recovered.

No very positive statements can be made from observations so limited; but as I have found all these different forms of casts present together only in these few cases, and as all but one have terminated fatally, I infer (1) that the combination is rare, and (2) that it indicates a very grave form of the disease. Although it has been abundantly proved by pathological examinations that casts are *formed* in the convoluted tubes, some authorities deny that they are ever found in the urine, it being, in the opinion of these observers, impossible for such cylinders, on account of their large size, as inferred from the comparative size of the tubes in which they are formed, to pass through the narrow loops of Henle. The force of this objection is considerably weakened by the fact that the epithelium of the convoluted tubes is much thicker than that lining the descending loops of Henle, and thus the disparity between the calibre of these different tubes is greatly reduced. And when the cortex of the kidney is the seat of congestion or inflammation the epithelium of the convoluted tubes is increased in thickness much more proportionably than the latter.

In speaking of the anatomy of the convoluted tubes, Charcot² says: "The cells which form this lining, as we know, almost coalesce; they are voluminous and leave in the cavity of the tube only a narrow lumen." Farther on he says, "In the descending limb of Henle's loop the epithelium suddenly undergoes a profound modification; we then find only, indeed, a tessellated and clear epithelium, swollen only at the level of the nucleus and entirely analogous to that presented by the blood-vessels." This is substantially in harmony with Flint's³ description of the minute anatomy of the kidney. If to the above anatomical facts we add the one in regard to a physical property of casts themselves, wherever produced, namely, that a certain amount of shrinkage takes place in them before they are dislodged from the site of their formation, it seems quite possible that they may be driven through the narrow looped tubes and subsequently appear in the urine. Clinical testimony in support of this opinion is not wanting. Charcot⁴ says that "the casts of the convoluted tubes can, indeed, pass through this narrow branch only with the greatest difficulty, and we cannot expect to find them *often* in the urine." Cornil and Ranvier assert that "it is certain that casts formed in Henle's loops sometimes pass into the urine, and it is probable that narrow casts formed in the convoluted tubules of the cortical substance may also be washed out by the secretion of urine." On the following pages, in describing the different forms of casts, they say "at times they resemble a corkscrew, having the shape of the convoluted tubules in which they are formed." Under the head of "Casts," Dickinson⁵ makes the following statements: "Casts of large diameter are seen, containing within themselves others of smaller size. In such cases the small cast has been formed in the upper or convoluted part of the tube," etc.

Tyson,⁶ after mentioning the theoretical objections advanced against the escape of casts from the convoluted tubes, and stating that it is easy for them to pass from the *intermediary* portion, says, "While there are difficulties in the descent of a cast from the cortex of the kidney, and while such descent is doubtless more rare, I do not consider it impossible." Now, casts formed in the con-

voluted tubes would probably retain the general shape of the mould in which they originate, as is true of casts from other parts generally, even after passing through the medullary portion of the kidney, and hence be pathognomonic. The small, crooked, spiral, or corkscrew-shaped bodies which I observed in the urine of the boy whose case I have herein detailed, as well as in that of the other similar cases referred to, I believe were formed in the convoluted tubes. They resembled those seen *in situ* in the cortex of the kidney, and correspond to the illustrations of Dickinson, Bartels, and others. If they are not formed in the convoluted tubes it is difficult to account for their shape. If they come from straight tubes, and their shape is a matter of accident, they should be seen oftener and in mild cases. Judging from my own observations, I should say that they are rarely seen, and that their presence is a symptom of very great gravity. As bearing on this subject, the following extract of a letter which I received from Dr. George L. Peabody, Pathologist to the New York Hospital, more than two months after I made the inquiries, is of interest: ". . . I have had the usual crop of diseased kidneys this winter, and can now answer your questions, I think, with more certainty and definiteness than I could have done before. In answer to your first question as to the comparative frequency of casts in the straight and convoluted tubes, I may say that in my experience they are much more common in the straight ones, and are frequently confined to the straight tubes of the pyramids. I can hardly say that it is rare to find them in some of the tubes of the cortex (other than the straight tubes of the medullary rays); but from the anatomical intricacies of the cortex I do not think that in any given case it is always possible to say whether the casts are actually in the convoluted tubes or in the intercalated tubes. In regard to your second question, I do not now recollect to have seen casts in the convoluted tubes in any case where they were not present in the straight tubes." In regard to the significance of granular casts they seem to be present at times in the urine in all forms of nephritis, and in all stages and all degrees of gravity of the disease. Certainly they are common enough in the milder grades of acute parenchymatous nephritis. If the urine contain a large number of blood-casts, it is a symptom of gravity.

(To be continued.)

THE BLUE MAN OF MISSOURI.—Dr. Thomas F. Rumbold reports in the *St. Louis Medical and Surgical Journal* the following history of a patient known as the blue man of Missouri: "Mr. J. S. F., aged thirty-three years, of Columbus, Mo. At the age of about fifteen years he took daily from five to ten drops of a solution of nitrate of silver of the strength of grs. xx. ad ̄j. This was continued for about five or six months; at the end of this time he noticed that his face and hands were getting a peculiar dark color. The color increased for some time after he discontinued taking the silver solution. The color of the integument of his face and hands at the present time resembles a No. 2 lead pencil mark, with a light sky-blue in it. A stove merchant, who happened to see him in my office, thought that his face and hands had the appearance of being colored with a light coating of stove-polish, which is really a very good description of his appearance, as the skin of the face, especially, has a marked polished appearance or a shine to it. The color is decreased during cold and dry weather, and increased during damp and hot days. The mucous membrane lining the anterior nares, the inside of the mouth, the lips, the under portion of the tongue, the soft palate, tonsils, pharyngo-nasal cavity, larynx, and vocal cords were all colored by the nitrate of silver, so were also the membrana tympani and the sclerotic coat of the eyes. The whole of his body was more or less colored, but not to so marked a degree."

HEMIANÆSTHESIA AND HEMIOPIA IN CEREBRAL SYPHILIS.¹

By L. PUTZEL, M.D.,

NEW YORK.

THE symptomatology of cerebral syphilis is almost as varied as that of hysteria, the most capricious of all neuroses. In the present paper I shall not attempt to enter into the general bearings of the topic, but shall merely call your attention to a complex of phenomena which is of such exceedingly rare occurrence in this disease that my acquaintance with the literature of the subject has made me cognizant of but one case bearing any analogy to it, and to which attention will be called further on. I suspect, however, that the symptoms in question are not so rare as the infrequency of reference to them might lead us to believe, but that this is partially accounted for by the fact that they are not alone usually unrecognized by the patient but also escape the observation of the physician unless careful search is made for them. None of my cases proved fatal, so that post-mortem demonstration was impossible, but the peculiar combinations of symptoms were so well defined that a tolerably exact localization of the lesion could be ventured upon. At all events, there can be no doubt that the symptoms in question were due to cerebral syphilis. The histories of the cases are as follows:

CASE I.—R. S., admitted to my wards in Randall's Island Hospital January 13, 1881, a native of this country, aged forty-seven years; her family history is unimportant; she is married and has had five children and two miscarriages. Three of the children died; one had an eruption appear upon the body which lasted until death at the age of nine months; the other two died in convulsions, one at the age of nine months, the other at four months. The patient states that her husband was dissolute in his habits.

She has had crying spells for which she could give no cause, and also a sensation of something in her throat and vague pains in her head, all of which symptoms passed off without treatment. About eight years ago she had a sore throat with a similar condition of the tongue and lips, and also lost a large quantity of hair from the scalp. Five years ago she had an iritis in the right eye together with sore throat; vision has been impaired ever since in this eye.

Seven years ago she began to suffer from muscular twitchings in the right leg, occurring during the night. In the spring of 1879 she first noticed loss of strength in this limb, accompanied by a sensation of cold on the outer side of the right thigh and leg. About the same time her attention was called to a dead sensation on the outer side of the right arm and hand, occurring during the night; five months later she also began to lose power in this limb. These symptoms had been preceded by occasional burning pains in this region. The power in the arm and leg continued to diminish very gradually until finally the patient was compelled to give up work. Five months ago she began to notice a loss of general sensibility over the entire right side of the body, and about the same time the sense of smell was lost in the right nostril. There has never been any disturbance of the functions of the bladder or rectum.

Present condition.—The patient is well nourished; has a rather flabby look; denies drink. There is nothing noticeable about the face; the muscles can be moved normally; the tongue is protruded in a straight line. The patient masticates better on the left side of the mouth than on the right.

Special senses: *Sight.*—Can read ordinary newspaper print at a distance of about twelve inches with the left eye and at about eight inches with the right. The right field of vision is much contracted.

¹ Read before the Section on Practice of Medicine of the New York Academy of Medicine, at a Stated Meeting held February 27, 1883.

Smell and taste.—Absent on the right side, normal on the left.

Hearing.—The ticking of a watch is heard at a distance of eight inches on the left side, and very slightly when pressed directly against the right ear.

Motion.—There is considerable loss of power in the right arm; the dynamometer can only be forced to fifteen on this side, to twenty on the left. The right side of the thorax lags somewhat during respiration; tenderness over the sternum on pressure. There is considerable loss of power in the right leg, but no muscular atrophy; the tibiae are tender on pressure. The patellar tendon reflex is increased on the right side.

Sensation.—Tactile sensation is diminished on the right side of the face, and also over the right upper limb, the diminution being most marked in the hand and fingers. Can feel nothing but large articles with this hand, and then is unable to recognize them by the touch. Over the right leg the patient feels only one point of the æsthesiometer, although the instrument is separated to its fullest extent.

Dr. D. C. Cocks, Ophthalmic Surgeon to the hospital, has kindly furnished me with the following notes of the results of three examinations of this patient's eyes:

April 22d.—Choked disks, most marked in the right eye; slight insufficiency of the interni; field of vision slightly contracted.

June 14th.—V. = $\frac{1}{10}$ with $-\frac{1}{8}$; the interni are weak, also the right externus; the patient states that she sees double with the right eye when the object is carried to the right and upward. Examination with the ophthalmoscope shows neuro-retinitis.

September 21st.—Left eye: temporal side of nerve looks atrophic, but the upper and nasal sides are still indistinct. Right eye: nerve indistinct. Patient was ordered the anti-syphilitic remedies, and soon showed considerable improvement. Smell is much improved and she now hears a watch at a distance of six inches on the right side. The field of vision has expanded slightly. Taste has not improved. She can now distinguish articles by feeling them. The muscular power of the right side has also increased; grip with the dynamometer, right hand 28, left hand 28.

April 1, 1881, the patient was discharged at her own request, greatly improved.

Diagnosis.—The occurrence of hysterical symptoms in this patient may, perhaps, lead to the suspicion that she suffered from hysterical hemianæsthesia, but this view may be discarded for the following reasons: The mildness of the hysterical symptoms which were really present; the absence of convulsive seizures and other phenomena occurring in grave hysteria; the gradual and regular onset of the symptoms; their persistence; the presence of organic changes in the optic nerves.

There can be no doubt, indeed, that the cerebral disease was organic in its nature, and the well-marked history of syphilis, together with the marked improvement under the antisymphilitic remedies prove the case to be one of cerebral syphilis. As is well known, this disease is characterized by various lesions, by gummata growing from the dura or pia mater, by gummatous meningitis, endarteritis with its sequences, and the occurrence of gummy growths in the substance of the brain. The development of the latter within the brain-substance, *i.e.*, not propagated from the periphery, is of exceedingly rare occurrence, and has been denied by a number of authors. I have had the good fortune, however, to observe a case of this kind in which a gumma was found in each corpus striatum, surrounded on all sides by brain-tissue. To this category I believe the case under consideration belongs, since all the symptoms can be readily explained by the formation of a gumma in the posterior portion of the white capsule on the left side, and, so far as I am able to judge, by a lesion in no other situation. The occurrence of softening in this region from vessel changes

is negated by the slowly progressive character of the symptoms, their long duration, and the marked improvement under treatment. The branches of the middle cerebral artery, which supply this portion of the brain, are terminal arteries, and vessel changes of such long duration would inevitably have led to disorganization of cerebral tissue, and a consequent incapacity for the restoration which occurred to a certain extent in this case. The existence of choked disks is also significant in this respect.

CASE II.—Jane O'N—, aged thirty-three years; domestic; admitted as prisoner from the Workhouse, September 19, 1881.

Family history.—Unimportant.

Previous history.—Patient has been a hard drinker, chiefly of alcohol diluted with water; was married at the age of fifteen years; had six children, all of whom, with one exception, died at the age of two to four years. Denies venereal. She was always healthy until two years ago, when diplopia developed, with turning inward of the right eye; about a week later the right eyelid and face in the neighborhood of the eye began to swell, and there were shooting pains in the ball of the eye and the head. Since that time these parts have been more or less swollen; at times the eye would be closed, then the swelling would diminish, but it has never been entirely absent. At the outset she noticed anæsthesia of the right side of the face, but after the lapse of six months there was marked hyperæsthesia of the upper half of the right side of the face and forehead and the anterior half of the right side of the scalp. This has continued to date, being much worse at times. She has had pain and ringing in the right ear from the beginning; during the last two or three months there has been more or less deafness in this ear.

About a year ago the legs got weak after standing for any length of time, the right more markedly than the left; there have been slight cramps in the limbs at night. About two months ago the right arm began to grow much weaker than the left, so that the patient was compelled to give up work.

Present condition.—The patient is fairly nourished. Marked tumefaction of the right side of the face, beginning at the lower border of the malar bone and extending to the upper part of the right side of the scalp and forehead; the right eyelid is swollen and partially closed. There is a perceptible heaviness and dragging of the right leg in walking.

Special senses: Hearing.—The patient hears a watch at six inches with the right ear, and two feet with the left.

Sight.—Left eye normal; the right field of vision is narrowed in all directions, markedly in a vertical direction, to a much less extent laterally. Spots are sometimes seen before the right eye, and, at times, vision is entirely lost for a short period. Dr. Cocks states that the right optic nerve shows evidences of neuritis.

Taste and smell are also markedly diminished on the right side.

Motion.—Considerable diminution of power in the extensors of the right arm and forearm, less of the flexors; dynamometer: right hand, 22; left hand, 40. There is slight paresis of the right lower limb.

Sensation.—Tactile sensation is abolished in the toes of the right foot; markedly diminished on the dorsal and plantar surfaces, to a less degree on the leg; it is abolished on the last phalanges of the right hand, markedly diminished on the front and back of the hand, less on the arm. Slight diminution of sensibility on the right half of the trunk except the infraclavicular region; abolition on the right cheek from the lower border of lower jaw to a horizontal line drawn from the lobe of the ear. Exquisite hyperæsthesia on the right side above this line. Sensation to pain, heat, and cold correspond to the tactile sensation; these sensations are all slightly delayed.

Reflexes.—The cutaneous reflexes are abolished on

the right side, normal on the left; all the tendon reflexes are normal.

Electrical reactions.—The faradic reactions of the muscles and nerves are equal on both sides; electro-cutaneous sensation diminished and delayed on the right side.

Diagnosis.—Syphilitic (?) periostitis of that portion of the cranium and face corresponding to the tumefaction; endarteritis of the left middle cerebral artery, producing softening of the internal capsule. The patient was ordered iodide of potassium gr. xv. and hydrarg. bichlorid. gr. $\frac{3}{32}$ t. i. d. After the lapse of two weeks there was marked improvement in the symptoms.

October 13th.—She complains of steady burning pain in the epigastrium with a tendency to vomit; states that her menses came on four days ago but stopped at once; has a sharp shooting pain in the left leg.

October 20th.—The shooting pains in the leg are increasing; an occasional shooting pain in the left thigh along the sciatic nerve; a feeling of crepitation under the patella. Increased cutaneous reflex in sole of left foot; with the exception of the hip-joint, the joints of the left leg are tender when pressed together; pain relieved on extending them. Tenderness over the transverse processes of the spine, chiefly on the left side, from the middle of the dorsal region to the upper border of the coccyx; this is most marked over the last lumbar and first sacral vertebrae. Marked hyperæsthesia over the left side of the trunk, beginning above at the middle of the dorsal region, and also over the left lower extremity. The right side is approximately normal.

The tumefaction on the head is rapidly disappearing. The dose of the antisyphilitic remedies was ordered to be doubled and the actual cautery applied, every second day, over the transverse processes of the spine on the left side.

Dr. W. O. Moore examined the eyes and found R. V., $\frac{15}{60}$; L. V., $\frac{20}{60}$; R. Snellen, I.; L. Snellen, IV. Accommodation good.

November 8th.—The iodide was increased to $\mathfrak{z}$ j. t. i. d.

November 12th.—The pains in the limb have disappeared. The patient has made a marked improvement, with the exception of the special senses, which remain as at time of admission.

December 2d.—Patient discharged.

The symptoms which developed late in the left leg may be attributed to spinal pachymeningitis below the middle of the dorsal region. Although syphilis of the spinal cord is a rare affection, a number of cases have been reported in which post-mortem examination showed the presence of lesions in the spinal cord and its membranes similar to those occurring in the brain.

In this case no direct history of syphilis could be obtained, but the occurrence of periostitis without any known cause, the irregular distribution of the cerebral and spinal lesions, and the prompt response to anti-syphilitic treatment, justifies the assumption of constitutional syphilis.

The question arises whether the disturbance of the special senses in this patient was peripheral or central in its nature. I incline to the former view, for the following reasons:

The disease began with diplopia from paralysis of the right sixth nerve, and this symptom, when isolated, is always peripheral in its character. The trigeminal and auditory nerves were the next to suffer, and the same remark holds good with regard to these. In addition, syphilitic periostitis of the cranial bones is often combined with pachymeningitis. But perhaps the strongest argument in favor of the peripheral nature of the special sense disturbance is the fact that vision was affected on one side alone. Were the lesion of the optic fibres central in its origin, it would undoubtedly have produced interference with vision in both eyes.

CASE III.—Cornelius J—, aged forty-seven; janitor, single; admitted December 23, 1881.

Family history.—A maternal uncle became melancholy and committed suicide; a brother and sister died of phthisis.

Previous history.—At the age of fifteen years the patient had ship-fever and small-pox; when sixteen years old had a chancre and buboes. At the age of eighteen he states that he had a true syphilitic eruption; also gives a history of enlarged glands, pain in the bones, etc. Began drinking when twenty years old, and has since indulged in protracted sprees from time to time. About two years ago, after he had been drinking for two weeks, the patient rose from bed in order to go to the closet, when he found that the left side was powerless and apparently dead. On the first attempt to step he fell and was carried to bed. Before the fall he was conscious, appreciated his condition, and called for help; after the fall he was unconscious for a few hours. It is stated that while in this condition he was asked by a physician with regard to sensation on the left side, but no evidence of sensibility could be obtained. Upon the return of consciousness, however, the left side was again almost normal as regards sensation and motion. A slight feeling of weakness remained in the left leg and has never disappeared, but the hand was normal. The patient left his bed the same day, feeling no worse than prior to the attack. For six months previously he had complained of pains in the head, and these have continued until the present time. A week later he returned to work and no further trouble was experienced until four months ago. At this time he went to bed one night feeling perfectly well, and, on the following morning, awoke with complete loss of vision, which lasted five minutes; he was then able to see the color of a friend's coat, but required assistance in dressing himself, being unable to see small objects, such as buttons, etc. He groped his way down stairs into the yard; is unable to say how well he could see, but knows that he could not depend on his vision. When he reached the yard, he fell upon his back and rolled on the right side, the left being powerless, and cried for help. He did not lose consciousness, but remembers being carried to his room, and was soon able to see better than when he went to the yard. After sitting in a chair for two or three hours, he rose, undressed himself, and went to bed. Eyesight was perfect then, and the left side caused no inconvenience to him while undressing. Upon the following morning he got up after a restless night, but could detect no trace of the attack of the previous day. The pains in the head were, perhaps, more severe than usual.

For upward of nine months he has had various attacks of more or less complete momentary loss of vision while walking in the street. At times he has walked directly against persons, and, on one occasion, fell into an open cellar, knocking himself senseless. He found himself in the New York Hospital when consciousness returned. About a month ago the patient noticed that his sight was very poor, and to this he attributes breaking several articles of glassware intrusted to his care.

Present condition.—The patient is a well-nourished, healthy looking man; appetite fair, bowels costive. There is a swelling in the left temporal region, and a short incised wound on the left supraorbital ridge, the result of running into a pillar in a dark cellar. No paralysis of the facial muscles; the tongue is protruded in a straight line and freely movable; the movements of the hands and feet show no perceptible loss of strength in these parts. The left triceps is weaker than its fellow on the opposite side. The dynamometer registers in the right hand 49, left hand 40. There is no difference in the power of the lower limbs, except that the flexors of the left thigh appear to be slightly paretic. The measurement of the limbs are the same on the two sides. The patella tendon reflexes are well marked and equal. The cutaneous reflexes are lost on the left side and normal on the right.

Sensation.—There is complete anæsthesia and almost

complete analgesia on the left side of the body, bounded exactly by the median line; sensibility to heat and cold is much diminished on this side, but not entirely lost; no delay of sensation. The right half is apparently normal. The patient suffers from a constant pain in the head, principally in the frontal region; this is the chief source of complaint.

Special senses.—*Hearing* is much impaired in the left ear; he only hears the tick of a watch at two inches on this side, while with the right ear it can be heard at a distance of twenty inches; no perforation.

Sight is impaired in both eyes, especially for near objects; he is inclined to close the left eye when unusually good vision is required. He states that the defect in the left eye is due to a pustule forming in the eye during his attack of small-pox; but no remains of this can be detected at the present time. He reads print at twenty feet with the right eye that he can only read at ten feet with the left eye. The pupils respond to light and show the reaction of accommodation. The left half of the normal field of vision is absent on both sides. The right half of the field of vision of the left eye is also considerably narrowed. Examination with the ophthalmoscope shows slight neuro-retinitis of both eyes.

Smell appears to be abolished on both sides.

Taste is also impaired, but no difference can be detected between the two halves of the tongue. Sweet substances are recognized, but quinine and other bitter articles produce simply a bad taste and cannot be distinguished from one another. A number of seconds elapse before any taste is appreciated. This patient was suddenly discharged without my knowledge, so that I am unable to describe the further course of the disease.

The *diagnosis* of this case is surrounded with great difficulties, and the localization of the lesion can only be made with a certain degree of probability. It seems to me most probable that the symptoms are due either to a diffuse lesion of the cortex of the right occipital lobe, perhaps gummatous meningitis with softening of the subjacent cortex, or more probably to a lesion of the posterior third of the posterior half of the internal capsule. I am inclined strongly to the latter opinion, on account of the very marked loss of general sensation.

CASE IV.—Richard B—, aged forty years; family history unimportant; about two years ago, patient had an attack of gonorrhoea; last June had some chancres, which were cauterized, but for which internal remedies were administered also. Last winter he had rheumatism (?) in both legs, for which he applied turpentine locally, and states that this application was followed by the suspicious pigmented spots which are now visible over both tibiae. At the present time has a slight enlargement upon the upper part of the right tibia, which is exquisitely tender on pressure. Also has two patches of eruption (in the palm of right hand and left forearm), which look like tubercular syphilides. About July 4, 1882, he became affected with a violent headache, which lasted uninterruptedly until near the middle of September (about five weeks after the beginning of his present illness).

August 1, 1882, while crossing the street in order to enter his house, the patient suddenly became dizzy and acted as if under the influence of liquor; he managed to reach home, but then lost the use of the right side and was carried to bed; he says that sight was lost for three-quarters of an hour (whether this loss of vision was real or merely apparent, and due to the intense vertigo, I was unable to determine positively). On the following day the power over the right side was restored and he became paralyzed on the left side; he also suffered from nausea and could retain nothing on his stomach; the bowels, which had been regular previously, became very much constipated, and since the attack he has had but one movement every eight to ten days; for the past five months micturition has been attended with some difficulty. Contracture and tremor of the paralyzed side

developed soon after the attack, and have been growing steadily worse ever since. About a month ago the speech became so thick as to be almost entirely unintelligible; this condition lasted four or five days, and then disappeared entirely.

Present condition.—The patient is a fairly nourished man; he presents well-marked nystagmus, which, according to the statement of his mother, existed from birth. The movements of the facial muscles appear to be normal; the tongue is protruded in a straight line and can be moved readily in all directions; speech entirely normal. Sensation is slightly dulled on the left side in the lower half of the face. Smell is impaired in left nostril; taste is also distinctly impaired upon the left half of the tongue, both anteriorly and posteriorly. Dr. D. C. Cocks, to whom I sent the patient for examination, kindly furnished me with the following report:

"DEAR DOCTOR—I have examined the eyes of Richard B—, but the fundus could not be examined in detail owing to the rapid nystagmatic movements of the eyes. First V. = $\frac{3}{8}$ with —30.

"The field of vision is somewhat contracted downward and outward in each eye. The ophthalmoscope shows one or two floating bodies in the vitreous, but no marked lesion of the fundus. Nystagmus probably congenital, but he has better vision than is generally found in these cases.

Yours, etc., D. C. Cocks."

Upon testing hearing, I found that there was a slight difference in favor of the left ear in detecting the ticking of a watch, but that there was a very marked difference in favor of the left ear in appreciating conversation.

Memory seems to be entirely intact; the patient appears intelligent, and states that he has detected no mental deterioration.

The left arm is flexed at the elbow and at the wrist and fingers. After considerable effort on my part, the limb can be extended completely; but this passive extension is attended with some pain.

The limb is almost completely paralyzed, the movements being extremely limited. Upon comparison with the right side, the limb appears to have undergone general atrophy. Measurements: right forearm, $10\frac{1}{8}$ inches; left forearm, 9 $\frac{1}{2}$ inches. The muscles are somewhat softer than those of the opposite side. There is slight anaesthesia of the entire limb, most marked in the fingers. The tendon reflexes are enormously increased, particularly those of the biceps and triceps; the mechanical excitability of the muscles is also increased markedly.

The loss of power in the left lower limb is much less marked than in the upper. In walking the limb is moved stiffly, and is not bent at the knee; movement is often attended by involuntary tremor. Atrophy of the lower limb is also evident. Measurements: right calf, $13\frac{1}{8}$ inches; left calf, $12\frac{3}{8}$ inches. The muscles are somewhat flabby, and the limb feels very cold to the touch. Sensation is diminished throughout the entire lower limb and to a more marked extent than in the upper. There is an enormous increase of the patellar tendon reflex and ankle clonus, the entire limb being thrown into violent spasmodic movements upon tapping the ligamentum patellae or the tendo-Achillis. The knee phenomenon can be produced also by tapping the tibia or the muscles of the thigh (these reflexes are also exaggerated considerably in the other limb).

In some of its features—viz., the evidences of descending degeneration of the lateral column (increased tendon reflexes and contracture) and of secondary atrophy of the anterior horns of the spinal cord (early muscular atrophy)—this case resembles very closely the history of a case which I had the honor of reading before this Section a year ago, and in which the diagnosis was confirmed upon autopsy. With regard to the cerebral localization, I must confess to an inability to make a diagnosis, unless we assume the occurrence of two lesions—one which has given rise to the loss of hearing on the right side, and concerning whose situation I am unwilling to offer any

opinion whatever; the other probably in the posterior part of the right internal capsule.

A comparison between this and the preceding case reveals an interesting diagnostic feature bearing on localization. Anatomical investigations, which have been confirmed by a few pathological facts, have proven that the anterior two-thirds of the posterior half of the internal capsule are occupied by the pyramidal (motor) tracts and the posterior third by the tracts for general sensation and special sense. In the preceding case, therefore, we may assume that the lesion involved almost exclusively the posterior third of the internal capsule, since hemianæsthesia and hemiopia were almost the sole symptoms, motion being unimpaired, while in the present case the lesion affects chiefly the anterior two-thirds of the posterior half of the capsule, and extends very little into the posterior third, since motion is affected most profoundly, general sensation to a moderate extent, and the impairment of sight is limited to a small part of each field of vision.

The following case reported by Dowse ("Syphilis of the Brain and Spinal Cord," p. 92) is the only one which I have been able to find in the literature of the subject which at all resembles those reported above:

"C. A—, aged thirty-three years, contracted syphilis when young. At the age of twenty-nine he began to suffer from attacks of headache, vomiting, and a sense of numbness of the entire right half of the body, but consciousness was scarcely if at all interfered with, neither was voluntary power. The fit commences with dimness of sight, leading to total blindness of the right eye, diplopia during the seizure, but immediately preceding it there was hemiopia (no retinal change). There were no fornications, but the right half of the tongue became numb, as well as the parts supplied by the sensory division of the nerve and pharyngeal plexus. Taste and smell were both lost on this side, and saliva flowed freely from the mouth. Then the tips of the fingers of the right hand became numb, and rapidly the whole of the right half of the body became involved. This condition usually lasted twenty to thirty minutes, the numbness departing inversely to its arrival. Between these attacks he says that he feels all right except that he is a little confused in his mind. The right half of the body during the fit is colder and paler than the left, and at ordinary times there is slight impairment of tactile sensibility and the special senses. He denied ever having had a fit, neither had he found his tongue bitten, or his body bruised when he awoke in the morning, but the pillow was always wet with saliva. I had him watched carefully at night, and there was no doubt whatever about his being the subject of epilepsy during sleep, but of this he was quite unconscious.

"The patient was cured by the administration of iodide of potassium in two-scruple doses every other night, with Donovan's solution three times a day."

The history of my first two cases illustrates a point with regard to the prognosis of cerebral syphilis of long standing, to which I desire to call attention, viz.: that the current opinion with regard to the ready curability of this disease should be modified to a considerable extent. According to my experience, the most we can hope for except in cases of simple syphilitic epilepsy (which are generally due to gummata of the dura mater or pia mater) is a considerable improvement in the symptoms and their maintenance at the minimum. In a certain proportion of cases, especially those due to lesions of the vessels, the disease terminates fatally despite all our endeavors. I may state, however, in this connection, that, during the last few years, I have seen much fewer autopsies upon fatal cases of cerebral syphilis and have observed a less number of cases in practice than in former years. I believe that this condition of affairs must be attributed to the greater length of time during which the profession now subject syphilitic patients to appropriate treatment. At least, no other cause appears

to me to be adequate to explain such a marked change as that to which I have referred.

A word with regard to the frequency of the disturbances of the special senses and of general sensation occurring in the cases reported above. The conclusion has been forced upon me by my clinical experience during the past year or two, that hemianæsthesia, either of the special senses alone or of these in combination with general sensation, is much more common in organic diseases of the brain than is generally supposed. I have observed these symptoms well marked in at least half a dozen cases of the ordinary form of hemiplegia, due either to hemorrhage or embolism, and in none of them were the patients aware of any sensory disturbance. In the present unsettled state of the question of cerebral localization, it may be well worth our while to bear this fact in mind, in view of the light which it may shed upon the subject, and to examine the condition of the special senses, as a matter of routine, in all cases of organic disease of the brain.

Since reading the above paper I have found a reference to the subject under consideration in Fournier's book "*La Syphilis du Cerveau*." After stating that syphilitic hemiplegia is complicated with hemianæsthesia in very exceptional instances, he narrates the following case:

"This woman presents a left hemiplegia of undeniably syphilitic origin. You will observe in her both motor troubles of an uncommon intensity and very marked sensory disorders. The entire cutaneous surface on the left side is absolutely anæsthetic to contact, pain, and temperature. The mucous membranes on this side are also insensible. Furthermore, you will find, on the left side, sight abolished, hearing almost extinguished, taste and smell very much enfeebled."

In conclusion Fournier places the lesion in the posterior third of the internal capsule.

In this case, however, the imperfect history does not permit us to decide whether the sensory symptoms may not have been of an hysterical character. It is a suspicious circumstance in this connection that the disturbance of vision was limited to the left eye. In intracerebral lesions, followed by affections of sight, both eyes are always affected. In the absence of any statements, therefore, concerning the condition of vision in the right eye, the question must be left undecided. Perhaps, as has been shown with regard to a number of cases of cerebral hemianæsthesia reported by Charcot and his pupils, hemiopia was really present but had been overlooked.

THE EFFICACY OF BROMIDE OF ETHYL IN SHORT OPERATIONS.—Dr. Chisolm thus describes the efficacy of the bromide of ethyl in operations on the eye:

"A little girl eight years of age, who had strabismus, was put on the operating table, and told that the folded towel containing a teaspoonful of bromide of ethyl would feel choky when placed over her nose, but that she should breathe it freely nevertheless. In perfect confidence she commenced to breathe freely from the towel placed over her face, and in twenty-two seconds by the watch she was fast asleep. The operation of dividing the faulty muscle did not occupy much more than one-half of a minute. After two minutes of sleep she awoke and expressed herself as not knowing what had been done. Within three minutes from the commencement of the inhalation, the child was perfectly awake and was ready to get from the table. When on the floor she walked at once to the chair, and within four minutes from the time that the anæsthesia was commenced, she was engaged in pinning roses into the front of her dress, with a composure which showed not only no present discomfort, but also a complete oblivion of the experience through which she had just passed. In less than sixty seconds by the watch, an ugly deformity had been painlessly, perfectly, and permanently eradicated."

CHLOROFORM NARCOSIS DURING SLEEP.

By JOHN H. GIRDNER, M.D.,

NEW YORK.

THE impression is very general, both among the profession and the laity, that if chloroform be inhaled by a person while asleep, that person may pass from a natural sleep to a chloroform narcosis without returning to consciousness. This is sufficiently proven by the frequent accounts published in the daily papers of burglars having chloroformed their victims while asleep, and also by the fact that from time to time medical men testify under oath that such a thing is possible.

It is to throw light on this subject that I write this article. The evidence which comes to us from the secular press, tending to prove that such a thing is possible, will, I think, appear at once to be of little value from the standpoint of scientific inquiry, because these reports are written by reporters who have no eye to establishing the truth or falsity of the theory, and if they did, are never in possession of the proper facts to enable them to speak with even a moderate degree of certainty. It is generally stated that the smell of chloroform was detected in the room the next morning after the robbery. The odor of chloroform does not remain many hours in a room, because it is so volatile, and if the odor is really detected it is far from just to argue from that fact that the occupants of the room had been placed under the influence of the drug.

As to the testimony of medical experts, I may say that I am not willing to accept their statements that a person may be chloroformed while asleep without being awakened, because the evidence on which they base this opinion is anything but conclusive. The few experiments which have been made by these experts were not reliable tests, because the parties on whom they experimented were aware that at a certain hour of a certain night the doctor would make the experiment, and a desire on the part of the subjects to have the experiment succeed may have been strong enough to tempt them to simulate narcosis. At any rate, no experiment of this kind can be considered as evidence one way or the other, unless the subject on whom the experiment is made is ignorant of it, and not a willing party to the affair.

The experiments which I here give in detail were made by another medical man and myself, and I may add that we had both had large experience in the administration of anæsthetics, and that every possible precaution was taken that no error should creep into the result. The persons on whom we experimented were entirely ignorant of our intention to administer chloroform or anything else to them while asleep, and, in fact, we had told no one of our intentions.

It will be seen, therefore, that these experiments were made solely with the desire of arriving at the scientific facts, and under the best possible conditions to that end.

At twelve o'clock on the night of January 31, 1882, I went to the hospital through a terrific snow-storm, and together with Dr. —, a house surgeon, we made the following experiments:

I.—A little girl, aged twelve, was sleeping soundly, breathing slowly and regularly. Chloroform was poured on a folded towel and held eight inches from her face, and slowly and carefully brought nearer. At the end of about three minutes she coughed, awoke, and sprang upright in bed.

II.—Man, aged thirty-two, sleeping soundly. Chloroform used as before. At the end of about three minutes he awoke, coughing and striking out with his hands.

III.—Man, aged thirty-five. Chloroform given as before. At the end of three minutes he awoke, coughing and attempting to remove the towel from near his face.

IV.—Man, aged thirty. Acted as the others: woke at the end of about three minutes, coughing and resisting.

V.—Little boy, aged eight. Awoke at end of two minutes, coughing and struggling.

Here, then, are five experiments, made under the most favorable circumstances, and on both children and adults, and in each case the subject awoke at the expiration of three minutes, or about the time the nervous system was beginning to be profoundly impressed with the drug; all awoke suddenly, with coughing and resisting, or attempting to tear the towel from near the face. These experiments must then be taken as *prima facie* evidence toward the establishment of the fact that it is impossible to transfer an individual from a natural to a chloroform sleep without an interval of perfect consciousness, during which he would be able to appreciate his situation, and if force were used to carry on the anæsthesia to unconsciousness, the person would still be able on awaking to recall to mind the person who used the drug.

While many will doubtless require a larger number of experiments before giving a decision, there are some who will see sufficient evidence in these five experiments to satisfy their minds that every experiment of this kind, made for whatever purpose, will have a like termination.

THE ECCENTRICITIES OF ATROPINE.

By G. STERLING RYERSON, M.D.,

LECTURER ON THE EYE, EAR, AND THROAT IN TRINITY MEDICAL SCHOOL, TORONTO.

CASE I.—Master M— was brought to me on March 5, 1881. He is a delicate child and an only son, of highly nervous temperament, dark hair and pale complexion. He complained of pain about the eyes after reading; watering of the eyes, slight congestion of conjunctiva and periodic alternating convergent squint. I diagnosed H = 1 D. with ophthalmoscope, and as he rejected all glasses, I ordered two drops of a solution of atrop. sulph., gr. iv., aq. dest., ʒj., to be dropped into eyes twice a day and to return in two days; this was at 10 in the morning. About 2 P.M. I received a message to go at once and see the child, as he was very ill. On arrival I found him covered with a rash closely resembling a scarlatinal eruption. The pupils were dilated ad max.; breathing quick, pulse hurried, throat dry and parched, with difficulty in speaking. He also complained of numbness of the extremities. I felt strongly inclined to give a hypodermic injection of morphia, but thought it prudent not to do so unless forced to it by the urgency of the symptoms, inasmuch as the parents were already sufficiently alarmed, and the proposal would not have helped to calm their fears. Upon inquiry the mother positively assured me that she had only put in *one drop* in each eye about half an hour before I was called. This lady was most intelligent, and I have every reason to credit her statement. The symptoms gradually subsided and in thirty-six hours the boy was playing about as usual. The mydriasis continued for some days, and there was partial paralysis of the accommodation for some weeks after. The patient made a good recovery.

CASE II.—In October, 1882, an infant, one year and a half old, was brought to me with congenital cataract. Proposing to dilate the pupil prior to needling, I dropped into the eyes two or three drops of a four-grain solution of atropine. Within fifteen minutes the child was covered with a scarlatinoid rash and it seemed to have difficulty in swallowing. The pupils only dilated sluggishly. The rash subsided gradually.

CASE III.—When assistant to the late Mr. Soelberg Wells at the Moorfields Hospital an elderly woman came to the clinic with spasm of accommodation and symptoms of irritability of eye, due to prolonged use at her trade as a dressmaker. I ordered atropine to be dropped in. In a few days the symptoms yielded, but after the atropine had been stopped for some time the pupil still remained dilated and fixed. The accommodation also was paralyzed. Eserine and electricity were used

with but little benefit, and when I saw her last, some months later, there was but little improvement.

CASE IV.—In the fall of 1880 an ex-postmaster, aged seventy-eight, consulted me with regard to senile cataract, and a week or so later I did a Moorfield's extraction in the left eye. Ordered atropine (gr. iv. ad $\frac{5}{16}$ j.) to be dropped in, and was horrified next day to find the lid much swollen and excoriated, and a sharp attack of conjunctivitis. There was a little pain about the eye. I could not make out iritis after a careful examination of the eye. The edges of wound looked well. I immediately stopped atropine and gave eserine sulph., gr. ij. ; aq. dest., $\frac{5}{16}$ j. The symptoms subsided rapidly, and beyond a somewhat persistent conjunctivitis I was not annoyed by any more unpleasantness on the part of the conjunctiva.

Remarks.—I am induced to give publicity to these cases of atropine idiosyncrasy for several reasons. Cases I., II., III. have a medico-legal aspect. It would not have been difficult to trump up a charge of malpractice in these cases, and their record in a medical journal of repute may be of assistance to the practitioner should he be so unfortunate as to be placed in such a predicament. It may serve also as a warning against the too free use of atropine in refraction cases, and I would strongly advise preliminary use of atropine in cataract cases as a safeguard against optic accident. Further, they serve to show how small a dose of atropine may in certain individuals produce severe constitutional symptoms.

MENTHOL VERSUS PAIN.

By D. M. CAMMANN, M.D.,

NEW YORK.

WHEN the temperature of the oil of peppermint is lowered sufficiently it deposits small, colorless, prismatic crystals. These are called peppermint camphor, or menthol. Menthol is only slightly soluble in water, but dissolves readily in alcohol and ether, and in oils both fixed and volatile. Until lately it has not been used in therapeutics, but strong oil of peppermint painted over the part has long been a favorite mode of treatment in China for gout and neuralgia. Menthol has antiseptic properties similar to thymol.¹

In a letter to *The Lancet*, Mr. Macdonald, a student at Edinburgh, records the use of menthol in a solution of one part to sixty of rectified spirits, in cases of facial neuralgia, and writes, "relief was had in from two to four minutes, and within one or two minutes at most, after this, the then existing attack was cured." He also recommends the application of the crystals on cotton wool in cases of toothache.² In all my cases the following formula was used :

R. Menthol $\frac{5}{16}$ j.
Alcohol $\frac{5}{16}$ ss.

M.

It may be painted on the part several times daily with a camel's-hair brush. No precautions are necessary in its use, except to keep the solution from the eyes. It is rather agreeable than otherwise, except when applied over a large surface it may cause a feeling of chilliness. Several of my patients now keep it always at hand, and apply it when they feel an attack coming on. One of my cases was a boy, seventeen years of age, who had suffered with intermittent fever. At the time of examination he had had no chills for several weeks, but since they had ceased he suffered with severe pains over the spleen, from which he was never entirely free. The spleen was found to be enlarged. He was told to paint the side with tincture of iodine. In a few days he returned saying the pains were no better. Menthol was then prescribed. A few days after the pain had entirely

disappeared. Another case is of a lady who has had facial neuralgia for several years. She has tried many drugs, including chloral hydrate, bromide of potassium, quinine, and chloroform liniment externally. She is always benefited by quinine. During the last attack she used quinine, and also menthol. She recovered more rapidly than from former attacks, the pain disappearing in a short time. She was surprised herself at the rapidity of her recovery.

In addition to the above I have used menthol in cases of lumbago, facial neuralgia, fugitive chest pains of pulmonary phthisis, intercostal neuralgia, pleurodynia, gastralgia.¹ In all the cases in which internal medication was beneficial, menthol seemed to hasten its action ; in some cases in which both external and internal remedies had been without avail menthol gave relief. In some cases it has failed, but I have been surprised to see that sometimes very obstinate cases have yielded to its influence. It has acted well where tincture of iodine, chloroform liniment, and other local applications have failed. Nor in many cases is the result only temporary ; the pain may return after the first two or three applications, but if the treatment be persisted in for a few days a cure may often be effected. It seems, then, that in menthol we have a drug of considerable value in some of the less dangerous but most troublesome ills that flesh is heir to.

A NOVEL MODE OF CLEANSING THE VAULT OF THE PHARYNX.

By G. FAIRFAX WHITNEY, M.D.,

NEW YORK.

F—, a railroad conductor, aged forty-six, presented himself at my clinic at the New York Post-Graduate Medical School, complaining of having been afflicted during the last four years with post-nasal catarrh. He also stated that he was continually annoyed by hard lumps of mucus collecting in the upper part of the pharynx, and that the only way they could be dislodged was by being scraped away with *the tip of his tongue*. Upon being requested to perform this feat, he, much to my surprise, depressed the base of his tongue and inserted its tip between the velum palati and the vertebral column. I was unable to perceive by merely looking through the mouth to what height the tip of the tongue reached, but by making an examination through the anterior nares I was enabled to see that the tongue approximated the vault of the pharynx, yet could not determine positively whether it came into actual contact ; but, judging from the patient's statement, am of the opinion that such was the case. The patient could readily move with his tongue a probe inserted through the inferior meatus, provided it protruded slightly through the posterior nares.

A rhinoscopic examination revealed no collection of mucus upon the vault of the pharynx, and the patient, when asked whether he could detect any, replied in the negative, adding that immediately before entering the room he had removed with his tongue a hardened lump which he had then expectorated ; but that though he could not detect any mucus, he could distinctly feel a depression with the tip of his tongue. This depression may have been a slight concavity of the vault of the pharynx immediately back of the pharyngeal tonsil, or it may have been the posterior nares. The anatomical structure of the parts was normal, with the exception of the frænum linguæ, which was merely represented by a lax fold of mucous membrane. The tubercle upon the anterior arch of the atlas was unusually prominent, and the patient could easily detect its presence with his tongue.

Remarks.—Though this case is, I believe, the only one of its kind reported, I do not doubt but that there are many more existing to which attention has not been

¹ The Lancet, August 30, 1879.

² Ibid.

¹ My thanks are due to Dr. David Magie for the report of several cases of the use of menthol.

called. It seems very probable that one whose frænum linguae has been severed in childhood can readily acquire the power of introducing the tongue into the upper pharynx. In the above-reported case there was no history of any such operation having been performed.

Progress of Medical Science.

DISSOCIATION OF THE AURICULAR AND VENTRICULAR RHYTHM.—Dr. Chauveau recalls the case (*Lyon Médical*, February 4, 1883) previously recorded by Dr. Figuier, of a man in whom the radial pulse indicated but twenty-four cardiac pulsations per minute, while the auricles contracted about sixty-five times per minute. The ventricular rhythm was perfectly distinct from that of the auricle, the two pulsations coinciding only occasionally and without any apparent regularity. Some cerebral symptoms were present, notably vertigo. The writer argues that this singular dissociation of rhythm was due to a bulbar lesion involving the roots of the pneumogastrics; for experiment has shown that if the right pneumogastric nerve be divided and the peripheral portion be slightly irritated, the ventricular systole is slowed, while the auricular contraction is unaffected.

RENAL INADEQUACY.—Under this title, Dr. Andrew Clark (*British Medical Journal*, February 24, 1883), describes a class of cases which, in some measure, he ventures to separate entirely from Bright's disease, in which the kidney, without any sensible alteration of structure that modern means of investigation will enable us to determine, cannot produce a healthy urine. Such kidneys produce a urine which, assuming the quantity to be a quantity of health, is low in density, and is deficient in solid constituents, principally the constituent of urea and its congeners. This condition may be regarded as a very early stage of Bright's disease, but the writer thinks it of practical value to recognize by a distinct name a state which may remain as it is during the whole period of life, which is nevertheless capable of removal, and which if unnoticed may lead to serious injury to the patient.

Such patients are characterized by three things particularly: 1. By a curious inability to properly repair damages done to them either by accident or by disease. 2. They not only repair damages slowly, but are peculiarly vulnerable; they catch cold, for example, easily, and get rid of it with difficulty. 3. One can never be sure of the result of the performance of an ordinary surgical operation upon them; they die from a simple operation by hemorrhage, or have an ordinary abscess opened and become pyæmic.

Dr. Clark says that he knows of no symptoms in the early stage whereby these cases can with certainty be detected. In general, however, he states that "When you get hold of a patient who is ill, suffering from dyspepsia or nervousness, having headaches, and complaining of malaise and weakness, who cannot sleep well, who cannot do his work very well, examine his urine, and if you find that the urine is low in density you had better proceed a little further, and be very precise, and get the urine of twenty-four hours, and if you find that it is under fifty ounces in quantity, that it has not a specific gravity of 1010, and that the urea in it is deficient in amount—under two per cent.—then, whether there be albumen in the urine or not, whether there be any casts or not, whether there be granular debris deposited or not, you may know with certainty that the kidney is not doing its duty."

It may not be that this defect is the cause of the patient's ill health, but if it is found in addition that an increase of food makes the patient worse, and that, within certain limits, a diminution of food makes him better, there need be little doubt of it. As these cases of renal

inadequacy progress if they be not well managed, that is, if the management be not adjusted to the fact that they are chimneys being choked, and that a roaring fire cannot be kept on, they develop exceedingly characteristic symptoms, symptoms so like those observed in myxœdema that they can scarcely be distinguished. Dr. Clark cites two autopsies on patients who presented the symptoms of renal inadequacy, one in the earlier, one in the later, stages, in which none of the gross appearances of renal disease were present.

In the way of prognosis it may be said, in regard to these cases, that if care be taken, if compensation be made for the defective kidney, they probably may go on indefinitely, that is, they may reach the full term of life allotted to man.

Treatment should consist in close attention to simple physiological laws and careful adherence to such rules in regard to diet, clothing, temperature, and exercise as are generally laid down for chronic albuminuria.

EXPULSION OF A CALCULUS THROUGH THE VESICO-VAGINAL WALL.—Dr. Polaillon reported to the Société de Chirurgie de Paris (*France Médicale*, February 17, 1883) the following case: A woman, seventy-two years of age, suffered greatly from pain, especially during the act of micturition. An examination per vagina was made, and a hard body being felt, the physician gave a diagnosis of carcinoma. One day the patient experienced more severe pains than usual, and passed some blood. Putting her finger into the vagina she felt a hard body, which she supposed to be a piece of bone, and which she managed by violent efforts to expel. It proved to be a calculus of oxalate of lime with a phosphatic crust. It weighed 4½ ounces, and measured 2¾ inches in length, 2⅝ inches in thickness, and 2½ inches in width. The patient was afterward lost sight of, and it was not known whether the vesico-vaginal fistula ever closed.

EFFECTS OF EXTERNAL TEMPERATURE UPON THE BODY HEAT.—Dr. Nasaroff has been experimenting upon rabbits to determine the effects of sudden elevation and lowering of temperature. The animals were first placed in a room the temperature of which varied from 100° to 130°. Partly grown or fasting rabbits responded more quickly to the influence of the hot air than did full-grown animals or those that had just eaten. The body temperature rose at first slowly, but when 110° was reached the increase was more rapid—about 3.5° in ten minutes. If the animal were removed quickly from the chamber when a temperature of 111° was reached, it recovered promptly. The only results of such an elevation were a momentary sinking of the temperature below the normal and a temporary albuminuria. In cases of death the striated muscular tissue as well as the liver and kidneys were seen to be darker than normal. There was also a stasis in the capillaries. In experiments upon the abstraction of heat, young and fasting animals responded more quickly. They were placed in water of 32.5° to 53.5°, and recovered after a lowering of the body heat to 68°, but a temperature of 60° was fatal. After numerous repetitions the animals acquired an increased heat-forming power and were less readily affected by the surrounding temperature. Nasaroff states that the effects upon the internal organs of sudden change of temperature are too insignificant to account for disease from "catching cold."

Drs. Richet and Rondeau have also been conducting somewhat similar investigations to determine the mode of death by freezing. The first change was noticed in the respiration, which became at first shallow and then irregular. Life could be preserved longer if artificial respiration were practised. Next the heart was affected, the pulsations becoming markedly slowed. When the temperature fell below 62° the nervous system became affected. The loss of the power of voluntary movements preceded that of reflex movements. The corneal reflex was lost before the muscular reflexes of the lower extremities. Sensibility to pain and electrical irritability

were also lost. Although the animal was apparently dead, it could often be resuscitated by warmth and artificial respiration. The pulse returns first, then reflex movements; respiration is next established, and last of all to return is the power of voluntary movements. The practical value of these experiments lies in the demonstration of the possibility of recovery in apparent death from cold by means of warmth and artificial respiration.—*Centralblatt für Klin. Medicin*, January 27, 1883.

MISLEADING CARDIAC MURMURS AND EXPIRATORY AUSCULTATION OF THE HEART.—Dr. Hamilton Osgood describes, in the *Boston Medical and Surgical Journal* of March 29, 1883, a cardiac murmur occurring independently of anemia or heart-lesion. The murmur was systolic in point of time, located in the pulmonary area, with but little propagation, and was soft in tone, yet with a suggestiveness of friction. The man, an applicant for life insurance, was the picture of health, not a trace of anemia, had never had rheumatism nor pleurisy, and never experienced the slightest dyspnea. The murmur was discovered to be more faint during expiration. Acting upon this suggestion, Dr. Osgood instructed the man to make efforts at expiration and then to hold his breath. When this was done the murmur was found to have disappeared. The author thinks the murmur was due to some slight irregularity of surface in the pericardium near the base of the heart. During inspiration the pulmonary pressure increased the friction created in systole, while in expiration pressure was removed. He recommends the practice of auscultation of the heart during forced expiration, when the lung is collapsed, and the heart rests more directly under the ear of the auscultator. True endocardial murmurs become more distinct during expiration, while murmurs like the one described disappear.

THE MECHANISM OF LACHRYMAL CONDUCTION.—In a monograph entitled "*Die Muskulatur der Thränenwege und der Augenlider*," published in Stuttgart, Dr. G. Krehbiel, of New York, embodies the results of a painstaking anatomical study of the lachrymal apparatus. He states that the tensor tarsi muscle arises by two roots, the anterior and inner root from the crest of the lachrymal bone, the other behind and external to the first. Immediately after their origin the fibres of the two roots become interwoven, enclosing in their meshes the canaliculi and the ducts of the Meibomian glands. Thus the tarsal portion of the orbicularis muscle is formed of intermingled fibres from both roots of Homer's muscle, but those from the inner root run mostly along the lower lid, and the others along the upper. The author thinks that the tensor tarsi should be regarded as a muscle distinct from the orbicularis. When in action it exerts a considerable compressing force upon the canaliculi, and in so doing occasions the normal periodical emptying of these tubes. It has nothing to do, however, with the expulsion of the contents of the lachrymal sac. The latter is covered on its lateral wall, for the most part, by an aponeurosis from which arise fibres of the orbicularis palpebrarum. The contraction of these fibres causes a widening of the lachrymal sac. Thus, at every closure of the lids, two synchronous actions are caused. The lachrymal sac is dilated by the fibres of the orbicularis, and the canaliculi are compressed by the tensor tarsi. The emptying of the lachrymal sac is occasioned by atmospheric pressure, which exerts its influence the moment the eyes are opened and the orbicularis is relaxed. When the eyes are open the canaliculi act like capillary tubes to suck in the tears. If an unirritating colored fluid be dropped into the outer corner of the eye and winking be restrained, its presence in the nasal cavity is very quickly made manifest.

TREATMENT OF GOUTY PAINS AND NEURALGIA BY THE EXTERNAL APPLICATION OF NITRATE OF SILVER.—Dr. Frommüller advocates the external use of nitrate of sil-

ver to relieve the pain of gout and certain neuralgias. He relates several cases in which this practice was followed by the most gratifying results. The solid stick is to be rubbed over the moistened surface for about thirty seconds. When the skin is dry it is to be covered with a compress of salicylated cotton, which should be removed once or twice a day until the blister is healed. The caustic is to be rubbed over the affected joint in gout, and in neuralgia over the point of exit of the nerve from the bone, when this is possible. In order to be effective, the irritation should be sufficient to cause an exudation beneath the epidermis.—*Memorabilien*, January 31, 1883.

DISTENTION OF THE STOMACH BY CARBONIC ACID GAS AS AN AID IN DIAGNOSIS.—The more frequent employment of this long-recognized method is advocated by Dr. Rosenbach as a means of determining more definitely the situation and character of tumors of the stomach and neighboring abdominal organs. He claims that we can by this means ascertain exactly the position of the stomach, and can determine the size and location of tumors of this organ. The borders of the liver and the gall-bladder are rendered more distinct. Tumors of the spleen can be more readily diagnosed and differentiated from those of the kidney. And lastly, we can study better the pulsating painful tumors met with at times in the abdomen. The author states that such tumor is, in most cases, the head of the pancreas pushed forward by the dilated aorta. When the stomach is distended the tumor disappears, showing that it lies behind this organ.—*Schmidt's Jahrbücher*, February 27, 1883.

TEMPERATURE OF THE JOINTS.—Dr. Redard has been conducting a long series of observations to determine the local temperature of the joints in health and disease, and has arrived at the following conclusions: The temperature of the skin overlying the joints may fluctuate through 7° to 10° from external causes. The local temperature of the joints falls in proportion to their distance from the body. It is always higher on the flexor than on the extensor surfaces, ranging in the larger joints from 87° on the latter to 96° on the former. Joint motion causes an increased temperature not only of the articulation but also of the whole limb. Continuous movements of flexion and extension of the ankle for five minutes will raise the temperature of the entire limb nearly a degree. Thermometry of the joints in diseases is of value only in the superficial articulations. In hæmarthros the temperature rises after the third or fourth day and remains more or less elevated according to the nature of the resulting inflammation. In traumatic joint suppurations the local temperature sometimes reaches the same height as the general, but is never seen to rise above it. In rheumatic, gonorrhœal, and puerperal joint inflammations there is a considerable increase of heat, frequently of the entire limb. In joint effusions following fracture of the long bones there is an increased temperature after a few hours. This would indicate that there is a contusion of the joint with an inflammatory tendency, and not a simple effusion. In white swelling the temperature of the surface over the fungous granulations is raised from $\frac{1}{10}^{\circ}$ to $\frac{2}{10}^{\circ}$ above that of the neighboring parts. In caries sicca there are no characteristic changes to note. In old ankyloses we sometimes find an elevation of from one to two degrees. This shows that the inflammatory process has not fully subsided, and may thus furnish an indication for treatment.—*Centralblatt für Chirurgie*, January 13, 1883.

FATTY NECROSIS.—Dr. W. Balser (*Deutsche Medizinisch-Zeitung*, February 8, 1883) states that there is in many people a growth of fat-cells in the neighborhood of the pancreas. In exceptional cases, usually in very corpulent persons, this attains to such a degree that the greater part of the abdominal fat necroses, and death ensues from hemorrhage induced by this necrosis.

THE MEDICAL SERVICE IN OCEAN-GOING STEAMERS.

THE act passed last year by Congress for the inspection of steamers carrying passengers to and from American ports does not attempt to control the arrangements for medical treatment and sanitary supervision to be exercised by the ship's surgeon. So long as the great majority of these vessels enter our harbors under a foreign flag, and the sanitary police of these harbors remains entirely in the hands of municipal or state governments not directed by a central national authority, any undue interference therewith might hamper the interests of the international ocean traffic, and result in a disadvantage to the immigrants themselves. But it is easily to be foreseen that with the revival of American steamboat travel, the increase of emigration from Europe in a geometrical proportion after the prospective opening of the Northern Pacific Railroad, and the accomplished connection of the southern roads, the question of protecting our great cities and the populations of the vast territories on this continent, against the importation of disease and the germs of widely spreading epidemics, will have to be faced resolutely by the representatives of the nation in Congress and the central executive power. An organized system of sanitary control and disinfection on uniform principles laid down by a federal law, and watched over by the national executive, may be imperiously demanded sooner than the present aspect of affairs might seem to warrant. The late Dr. Woodworth, of the United States Marine Hospital Service, in his paper on Quarantine, read before the International Medical Congress of Philadelphia in 1876, has pointed out that "the endemic homes of cholera and yellow fever are the fields which give the greatest promise of satisfactory results to well-directed and energetic sanitary measures, and to this end an international sentiment should be awakened, so strong as to compel the careless and offending people to employ rational means of prevention." We fear it will be a long time before any international measures of this kind will be universal and efficient, whilst we insist that every national government has the right and the duty to protect its citizens by the most stringent regulations which science suggests and self-preservation dictates. Everybody who has read in Rapp's history of German immigration into the United States, how, during the seventeenth and eighteenth centuries small-pox and typhus fever were rife in the crowded vessels from Antwerp, Rotterdam, and other

ports, tossing for months on the ocean, and how these diseases were sown broadcast among the populations of the North American colonies, will admit that, *mutatis mutandis*, the same danger exists still to some degree. Under the present political and social straits of European states, with England commencing to ship her starving Irish subjects wholesale at reduced rates "to the Canadian fields of promise," with the experiences of the New York Emigration Commissioners, as laid down in the facts published in their yearly Reports at the time of the Irish famines, the great epidemics of cholera and the small-pox visitations in different European countries, the medical profession of the United States should timely consider how to strengthen the hands of the hygienic superintendents in passenger vessels, and of the health officers of ports of entry, in order to prevent and check at the outset all dangers to the public health coming from abroad. We have but to call in mind, in connection with the necessity of such measures the very stringent quarantine regulations adopted by the British self-governing colonies, especially the Australian and African, in consequence of repeated importations of contagious diseases into these young and prosperous communities by half-starved immigrants.

"The supervision of ocean-travel ought to be directed to securing good sanitary conditions for vessels at all times, out of as well as in port" said Dr. Woodworth. We must add that the supervision ought to begin at the ports of embarkation before the immigrants come on board. It was the merit of the late surgeon-general of our national mercantile marine service, to have first inaugurated a system of consular reports by telegraph from those ports. The medical inspections by the government officers of the European countries are notoriously made in a hurry, and are something of a sham. Competent voices have been raised for the establishment of a sort of quarantine lasting a few days before the sailing of the vessel in times of epidemics. This may be unfeasible, but whilst the ship is afloat there are two conditions of guarantee which ought to be complied with. The ship's doctor ought to be an experienced and an authoritative officer, to whom full power is given to order and supervise the inspection and disinfection of the effects and baggage of the passengers. For the latter purpose there ought to be on board a hot-air disinfecting compartment supplied with steam from the engines; there ought to be also proper bath-rooms in all passenger vessels. Now that the importance of the "germ theory" is fully estimated, and its bearings acted upon in the sanitary and therapeutic arrangements of surgical hospitals and infirmaries for contagious diseases, in phthisical and lying-in wards, it is time that the hygiene of sea-going vessels become remodelled on the hints long ago given by all experienced medical officers of the naval and mercantile marine services, but hitherto often unheeded by ignorant or headstrong commanders, or avaricious shipowners and companies greedy for dividends. The position of the doctor in passenger ships becomes more responsible and more important to the whole community under such circumstances. In the Army and Navy the importance of the medical service has been recognized in this country and in Europe after the teachings of great wars and their sufferings. Nothing short of a public calamity may do

the same in regard to the mercantile marine. It has been contended that the nation which takes the lead in securing the lives and health of passengers at sea, will take the first rank on the ocean, and secure the greatest commercial advantages to its shipping. We believe there is some truth in such a saying, and we claim for the ship's doctor a share in bringing about an increase of safety to the ocean traveller, and to the public on shore.

THE DISCUSSION OF THE NEW CODE IN THE ACADEMY, AND WHAT CAME OF IT.

THE proceedings at the Academy of Medicine on Thursday evening of last week were of a character to bring the blush to the cheek of every honorable member of the profession, whatever opinion he may hold concerning the Code or the question that was before the meeting.

Certain resolutions, designed to commit the Academy to a decision in a matter concerning which its members hold widely differing views, and which is seeking its legitimate solution elsewhere, were prepared in secret, brought without notice before a regular meeting, secretly packed with partisan supporters, and rushed without debate to a hasty adoption. Members who asked only for time to discuss the question and for notice to other members of the question to be discussed were received with hisses and their protests with jeers.

The trick, worthy of a machine politician, carried with the manners of a ward primary in a society one of whose declared objects is "the advancement of the character and honor of the profession!"

And then, with a fatuity which, however common its manifestations in the seconder of the motion, has not heretofore been suspected in the mover, a motion was made to reconsider, and then another to lay this one on the table, this being a parliamentary device to dispose finally of a motion. As if any final parliamentary disposal of a *motion* could prevent reconsideration of a *subject*. Such a move might avail to delay where long preliminary proceedings were necessary before a motion could be brought to a vote, but in such a case as this it would be gross flattery to call it even puerile. It served, however, to bring out the two following remarks, as reported elsewhere:

Dr. Agnew asked: "Then the object is to throttle this Academy?"

"Undoubtedly it is," said Dr. Flint, Jr.

The members of the Academy may well cry "Pause," and hesitate to sanction such methods—to follow such leadership. And we believe there are many, even among those who are heartily in support of the old Code, who will not allow their honorable reputations to be smirched by a tacit acceptance of the acts to which we have referred.

MEDICAL EDUCATION IN CANADA AND CHURCH INFLUENCES.

FOR many years back Laval University, of Quebec City, has been struggling against effects of the gradually increasing commercial depression which has attended that city. Its students in medicine became fewer and fewer each year; and, some three or four years ago, the university conceived the idea of opening or establishing a branch called a "*Succursale*," in Montreal, the largest

and most prosperous city in the Dominion. In this way the university hoped to improve its condition by drawing to its doors students from the Montreal district. Up to this period this district had supported the "Montreal School of Medicine," latterly known as "Victoria College," which institution being refused affiliation with Laval some years ago, had affiliated itself to the Victoria University of Coburg, a Methodist institution. This affiliation gave Victoria College in Montreal power to grant degrees in medicine to its students, otherwise it could not have done so. This relationship, however, of Victoria College with a Protestant university, was not pleasing to the Roman Catholic clergy; they wished to establish a purely Catholic institution of their own with university powers. Laval, as before stated, taking advantage of this feeling (some three or four years ago), opened a branch of its medical faculty in Montreal, and induced several of the teachers in Victoria College to give up their positions and accept similar ones in its faculty.

Open warfare now began between Laval University of Quebec and Victoria College of Montreal, and a suit in law was taken by Victoria against Laval to prevent it establishing its branch faculty of medicine in Montreal. This suit was carried to the Privy Council in England and decided by that tribunal in favor of Victoria College, saying that the charter which Laval possessed gave it power only to grant degrees in the Quebec district, and not elsewhere; so that all the degrees issued up to the present time by Laval in Montreal are illegal documents. Laval University now represented the matter to the Pope in Rome, so also did Victoria College. The Pope, after hearing both sides, declared in favor of Laval, reversing the former judgment of the Privy Council in England; and not only gave Laval full power to establish its "*Succursale*" in Montreal, but caused Victoria College to sever all relationship with the heretic institution in Coburg, thus throwing her back to her old position of a teaching school with power to issue a diploma only, and not the degree of M.D. His Holiness also issued a command to the faithful to assist Laval in every way, and all Catholic students to avoid Protestant institutions of any nature whatsoever. He also caused Victoria to withdraw all hindrance to the prosperity of Laval. But now comes the most extraordinary part of all: "The College of Physicians and Surgeons of the Province of Quebec," a lawfully incorporated examining body, before which all men seeking a license to practise medicine and surgery have to appear and obtain such license, simply upon producing a college diploma or university degree from a lawful and recognized institution—this body has all along accepted, and does so still, this illegal document issued by Laval University in Montreal, and grants to its graduates a license to practise.

So much for the colleges; now a few words about the part the hospitals played in the matter.

The "Hôtel-Dieu," the largest charity in Montreal, has always been the clinic of Victoria College. It is conducted by, and belongs to, an independent ecclesiastical order of sisters or nuns, and they have the power to offer or refuse teaching facilities to whatever school they wish. Now, when those gentlemen on the staff of the hospital who went over from Victoria to Laval openly

declared themselves in favor of Laval, the nuns informed them that their services were no longer required, and in fact struck their names from the hospital staff register. These men were now in a difficult position, because they had no hospital material to instruct their students with; so they put their shoulder to the wheel and originated the present flourishing "Notre-Dame Hospital," which is supported by voluntary contributions from all good Catholics, and has the recognition of the Pope and Catholic clergy. While this hospital was being fitted up, the Montreal General Hospital, in its usual liberal and generous way, admitted the Laval students to instruction within its walls, and issued certified tickets to attending students by the clinical professors of McGill University. The matter now stands thus: the Victoria College students and professors are the guests of the nuns in the "Hôtel-Dieu Hospital," and these nuns refuse to countenance in any way the professors or students of Laval, notwithstanding the urgent request of the Pope to do so. The "Notre-Dame Hospital" is the clinic of Laval University students, and is maintained for their use. How matters will be reconciled it is impossible to say. Laval is an illegal teaching body in Montreal, and Victoria College being stripped of her affiliation to the Coburg University, lives in the hope that she may succeed in becoming again affiliated to some Catholic university—there is one in Ottawa, and one in Manitoba—and in this way regain her power to grant university degrees, and at the same time conform to the wishes of the Church.

A JEALOUS WATCHMAN AND A RELIGIOUS HERALD ON QUACK REMEDIES.

AFTER-dinner speakers and commencement orators annually tell us of the close and beautiful harmonies in the work of the doctor and of the clergyman. We have wondered why these gentlemen have not sometimes pointed their rhetoric with journalistic illustrations, and shown us how harmoniously medical announcements work in with fervent piety in the columns of our religious weeklies.

The Watchman is a Boston paper, whose motto on the first page is: What of the Night? The Morning Cometh; on the last, "Yours for Health."

This *Watchman* has written an editorial in which it states that the careful aim of its editor is "to guard jealously its advertising columns," especially, as it says later, as regards "patent medicines." Our contemporary then proceeds to argue that some patent medicines are good, that they can be advertised properly, and ought not to be called quack medicines; it finds also much comfort in a similar position taken by the *Richmond Religious Herald*. These twin journalistic ornaments of religion, and stipendiaries of Lydia Pinkham, *et id. om. gen.*, assert that they cannot test all the mixtures they advertise; they do not endorse them editorially, and there probably is some exaggeration in their claims; their readers should be judicious in buying.

The reasoning adopted sounds finely, but while reasoning for one thing they practise another. The position taken by *THE RECORD*, which is, we believe, that of all just and sensible men, is this: There is a large number of diseases, such as consumption, cancer, Bright's disease, certain catarrhs, surgical maladies, for which there is

generally no cure and never any specific. These things are matters of common and accepted belief among all educated doctors, and they should be known to journalists and editors who, like our religious brethren, assume the responsible position of advertising all sorts of medicines and quacks.

Observe now the inconsistency, and, we will hope, ignorance, of our esteemed contemporary *The Watchman*. We are told that "it guards jealously its advertising columns." In these same guarded columns, we observe first, and with chaste rapture, that the immortal Lydia, Goddess of the Replaced Womb, occupies a considerable space in telling what is for the most part palpably false and impossible. Another party announces a "surest cure for all kidney diseases"—diseases which are not cured by any single medicine or measure. Dr. X advertises the "radical cure of epilepsy, even its worst cases;" Dr. Y announces a positive cure for consumption. Certain bitters will "cure dyspepsia, indigestion, malaria, and weakness." The C. and C. pills "really do cure sick headache, neuralgia, paralysis," and other trifles of a like nature. We note also a sure cure for "pimples," and another for rheumatism, neuralgia, and gout.

Most extraordinary of all, we find in these "jealously guarded columns" an advertisement for the cure of gonorrhœa, which is new, quick, and complete in four days! Is this a religious necessity? Do subscribers want it? *Watchman*, what of the night? Does the morning come with this?

We need not say anything further about the magical remedies for coughs, and asthma, about the "radical cure for catarrh," or of the two hundred New England clergymen who, says our watchful contemporary, have spontaneously testified to the superior excellence of the sarsaparilla troches.

The Watchman is no worse than many of its brother journals, though few go so far as to provide for the nocturnal indiscretions of its readers. It does, however, announce to its subscribers, whom suffering makes credulous, that there are cures for incurable diseases, specifics for troubles that cannot be relieved by specifics; and the whole tendency of its two or three columns of quack advertisements is doubly injurious. They help bolster up impostors, they deceive and very likely injure in purse and body the readers.

But these advertising columns are well-paid for, hence editorial sophistry and shame to the cause of religion.

HOW TO MAKE AN AUTOPSY.

THE remarkable studies of Professor Beneke, a notice of which appeared in *THE RECORD* some time ago, have given a new impulse and interest to the studies of the post-mortem room. The Massachusetts Medico-Legal Society, in a report by Dr. Bowditch, a year ago, called attention to some of Beneke's work as furnishing a model of what might be done by others in this direction. We quote here the conclusions especially referred to, since some of them are sufficiently instructive and significant to bear repetition:

"1. Before the period of puberty the aorta is *smaller* than the pulmonary artery, after this period the relation begins to be reversed, and in advanced life the aorta is always *larger* than the pulmonary artery.

"2. The aorta and pulmonary artery are absolutely smaller in the female than in the male, but relatively to the length of the body there is scarcely any difference between the circumference of the arteries in the two sexes, while the heart in females is absolutely as well as relatively a little smaller than in males.

"3. In adult males the volume of the lungs is greater than that of the liver; in adult females the reverse seems to be true.

"4. In men the volume of the two kidneys is nearly equal to that of the heart; in children it is greater.

"5. Children have a relatively larger intestinal canal than adults.

"6. A sudden increase in the size of the heart occurs at the period of puberty.

"7. The iliac arteries diminish in size during the first three months of life.

"8. The cancerous diathesis is, in the majority of cases, associated with a large and powerful heart and capacious arteries, but a relatively small pulmonary artery, small lungs, well-developed bones and muscles, and tolerably abundant adipose tissue.

"9. Pulmonary tuberculosis is often associated with an unusually small heart.

"10. In constitutional rachitis the heart is generally large and well developed; the arteries are also large."

Taking the above as a text also, Surgeon-General Crane, of the Army, has recently issued a circular of information regarding the methods of making an autopsy. He gives a model form of record of autopsy, which is essentially the same as that of Dr. Bowditch. To this is appended a list of instructions, from the same source, regarding the best methods of making careful autopsies. Most of the hints given are familiar to those in the habit of making post-mortems; but many of the points dwelt upon, even if familiar, are certainly quite ignored. The object of the investigator is, of course, first to find and verify the cause of death. And this in most cases ends the inquiry. Much more, however, could and should be done. The volume measurement of organs, their weight, the measurements of blood-vessels, of limbs, and body height, the length and capacity of intestines; all these and similar points are, as a rule, left out even in hospital record-books. Yet out of data like these some most important conclusions may be drawn.

We are gratified to observe how quickly the new Surgeon-General has learned the value of systematic and complete autopsical records. Some such model as that furnished by Dr. Bowditch should be adopted throughout the country in institutions where these records are kept.

PNEUMONALGIA: AN OLD NAME FOR A NEW DISEASE.

DR. R. R. DASHIELL, in a series of articles published in the *Nashville Journal of Medicine and Surgery*, upon the diseases of the Forked Deer and the Hatchie River Valleys, describes, under the name of pneumonalgia, a "symptom-complex" characterized by a kind of malarial congestion of the lungs. He says:

"Persons suffering from a protracted spell of intermittent fever, or such whose constitutions have been much broken or much impaired by repeated attacks, are frequently the subjects of a periodical painful stricture

across the breast, or sharp shooting pain through the chest, dyspnoea, and a short dry cough, though this in some cases is moist, attended with mucous expectoration in certain individuals, and sanguineo-mucous in others. I have seen the sanguineous expectoration in two cases amount to a hæmoptysis, the hemorrhage in one case coming on every evening, and in the other every other morning, in both cases preceded by chills, followed by painful stricture across the chest, accelerated, quick, small pulse, hot skin, flushed face, difficult breathing, and cough, with bloody expectoration, succeeded by a crisis of sweat. This form of affection I choose to denominate pneumonalgia, believing it to essentially consist in a neuralgic condition of the pulmonic plexuses, occasioning or inviting an afflux of blood to the pulmonary structure."

There are several objections to Dr. Dashiell's terminology and pathology. The term "pneumonalgia" has already been appropriated as a synonym for angina pectoris. Again, although the trouble may be a neurosis of the sympathetic nerves supplying the posterior pulmonary plexus, the essential disturbance is a vascular, not a painful one. From a clinical point of view Dr. Dashiell's contribution is interesting, and no doubt correct.

News of the Week.

CENTRAL PARK AS A SOURCE OF DANGER TO HEALTH.—We are told by the Park Commissioners that the ponds in Central Park are unquestionably a source of danger to the neighborhood. At a recent meeting of the Commissioners an elaborate report was made upon the subject.

"It is a fact," says the report, "too well recognized and understood to be contradicted, that of late years a considerable portion of Central Park, more especially some of the ponds of water, have become sources of malaria, whose unwholesome effects and influence have extended quite beyond the limits of the Park itself, to such an extent as to have given rise to numerous complaints and earnest remonstrance from the residents in the vicinity. There are within the Park six ponds, independent of the Croton reservoirs. These six ponds have a total area of 43½ acres. The total area of the reservoirs is 142 acres. Of the ponds, the one at Fifty-ninth Street and Fifth Avenue, being the nearest to residences outside of the Park, is the one that is most complained of. The area of this pond is 4½ acres. Its height above tide-water is 26 feet, but the others out of the six are lower in altitude. It has a drainage area within the Park of about 160 acres. At the present time the pond in question receives its chief supply of water from three sources, first, the direct surface drainage of all the area of open ground immediately contiguous to it; second, the water collected from the walks and roads lying within its drainage area; third, the water brought to it in brick conduits or sewers that find at this point their lowest outfall. . . . So strong and active is the organic matter in the pond that vegetation is constantly forming on the surface, while the large amount of ammonia discharged into it from the roadways creates the most pungent and offensive odors. The low situation

of the pond, surrounded by high ground and dense vegetation on the south, excluding the sun to a large extent, gives a dank, unwholesome aspect to its surroundings. Furthermore, the soil saturation of the borders of the pond where there is no rock adds largely to the possible chances of malaria."

THE AYES AND NAVS AT THE NEW YORK ACADEMY OF MEDICINE.—On Dr. Agnew's motion to lay upon the table the preamble and resolutions offered by Dr. Austin Flint, Jr. [see page 471]:

Ayes.—C. R. Agnew, W. T. Alexander, W. R. Birdsall, C. E. Billington, R. C. Brandeis, W. M. Carpenter, W. M. Chamberlain, W. F. Cushman, B. F. Dawson, J. H. Emerson, T. A. Emmet, G. H. Fox, V. P. Gibney, H. J. Garrigues, H. Griswold, H. T. Hanks, E. D. Hudson, Jr., A. S. Hunter, W. H. Katzenbach, E. L. Partridge, O. D. Pomeroy, D. B. St. John Roosa, C. D. Scudder, A. A. Smith, A. H. Smith, C. D. Varley, J. S. Warren, D. Webster, R. F. Weir, W. Gill Wylie—30.

Nays.—J. G. Adams, J. Anderson, J. H. Anderson, W. B. Anderton, E. S. F. Arnold, G. C. Arnold, W. B. Blakeman, F. H. Bosworth, F. A. Burrall, E. O. Cowles, A. Dubois, E. Eliot, J. O. Farrington, M. J. Fleming, A. Flint, A. Flint, Jr., J. Foster, G. Frazer, J. P. Garrish, H. Gomez, O. A. Gorton, J. W. S. Gouley, G. Griswold, J. H. Hinton, A. Hodgman, S. T. Hubbard, N. C. Husted, F. E. Hyde, J. E. Janvrin, E. G. Janeway, E. A. Judson, R. P. Lincoln, J. Linsly, W. T. Lusk, M. McLean, A. W. McLeod, J. A. Monell, H. D. Nicoll, E. H. Peaslee, P. B. Porter, S. S. Purple, H. F. Quackenbos, I. B. Read, E. Saunders, L. A. Sayre, L. H. Sayre, J. Shradly, J. L. Smith, I. E. Taylor, C. S. Ward, E. F. Ward, J. W. Warner, F. V. White, O. A. White, W. T. White, L. M. Yale, Wm. Young—57.

On the adoption of the resolutions:

Ayes.—J. G. Adams, J. Anderson, J. H. Anderson, W. B. Anderton, E. S. F. Arnold, G. C. Arnold, W. B. Blakeman, F. H. Bosworth, F. A. Burrall, E. O. Cowles, A. Dubois, E. Eliot, J. O. Farrington, M. J. Fleming, A. Flint, A. Flint, Jr., J. Foster, G. Frazer, J. P. Garrish, H. Gomez, O. A. Gorton, J. W. S. Gouley, G. Griswold, J. H. Hinton, A. Hodgman, S. T. Hubbard, N. C. Husted, F. E. Hyde, E. G. Janeway, E. A. Judson, R. P. Lincoln, J. Linsly, W. T. Lusk, M. McLean, A. W. McLeod, J. A. Monell, H. D. Nicoll, E. H. Peaslee, P. B. Porter, S. S. Purple, H. F. Quackenbos, I. B. Read, E. Saunders, L. A. Sayre, L. H. Sayre, C. D. Scudder, J. Shradly, A. A. Smith, J. L. Smith, I. E. Taylor, C. S. Ward, E. F. Ward, J. W. Warner, F. V. White, W. T. White, L. M. Yale, Wm. Young—57.

Nays.—C. R. Agnew, W. T. Alexander, W. R. Birdsall, C. E. Billington, R. C. Brandeis, W. M. Carpenter, W. M. Chamberlain, W. F. Cushman, B. F. Dawson, J. H. Emerson, T. A. Emmet, G. H. Fox, H. J. Garrigues, V. P. Gibney, H. Griswold, H. T. Hanks, E. D. Hudson, Jr., A. S. Hunter, E. L. Partridge, O. D. Pomeroy, D. B. St. John Roosa, A. H. Smith, C. D. Varley, J. S. Warren, D. Webster, R. F. Weir, W. Gill Wylie—27.

OFFICE THIEVES.—Two miserable-looking, dirty Irishmen, evidently office thieves, are going about the city representing themselves as Cincinnati physicians, sufferers from the flood. One of them says his name is Donnelly.

DEATH OF DR. J. C. PALMER.—Medical Director James C. Palmer, on the retired list of the Navy, died in Washington, April 24th. He had seen thirty-eight years of active duty in the Navy, and was put upon the retired list in 1873.

TYPHUS FEVER IN NEW YORK.—The City Sanitary Superintendent announces that fifteen cases of typhus fever in a very mild form have been discovered among the children in St. Stephen's Home in East Twenty-eighth street, near Third avenue.

ENDORING THE U. S. MARINE HOSPITAL SERVICE.—The New Orleans Board of Health recently passed resolutions unanimously requesting the President to place the Congressional appropriation for the suppression of epidemic contagious diseases, in case it should be required, in the hands of the Marine Hospital Service of the Treasury Department. A telegram from New Orleans states that the Boards of Health of all the Gulf ports will adopt the same course, and the National Board of Health will not have a foothold at any trade point in the Gulf of Mexico.

DR. H. S. TANNER, whose abstinence from food for forty consecutive days in 1880, in New York, caused so much astonishment, is now a resident of Jamestown, N. Y., where he is engaged in the practice of his profession and in manufacturing patent medicine.

Reports of Societies.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Eighty-fifth Annual Convention, held at Baltimore, April 24 and 25, 1883.

(Special Report for THE MEDICAL RECORD.)

FIRST DAY—APRIL 24TH.

THE great event of the year with Maryland physicians, more especially those of Baltimore, is the annual spring convention of the Medical and Chirurgical Faculty of Maryland, an organization incorporated by the Legislature of the State in 1799, and bearing an analogy to the State Medical Societies elsewhere, but distinguished from them in many respects, both in its object and present working.

The Convention of 1883 was called to order in Hopkins Hall, Johns Hopkins University, on Tuesday April 24th, at 12 M., by Dr. William M. Kemp, of Baltimore, President. Seventy-two members answered to their names on the call of the roll.

After prayer by Rev. Charles S. Albert, and the reading and adoption of the minutes of meetings held during the last year, the President delivered his address.

PRESIDENT'S ADDRESS.

He began by congratulating the society on its present prosperity and favorable prospects. His connection with it, he said, extended back over more than half the years of its existence. He then took up the subject of the importance of observation as contrasted with theory in the advancement of medical science. The most prominent epochs in its history correspond with revivals in the laborious and protracted observation and classification of facts. He illustrated this by reference to the lives and labors of Hippocrates, who perhaps gave the first impulse to true medical science; of Galen, whose influence retained its impress on medicine for nearly fifteen hundred years; of Rhazes, the great traveller, who gave to medicine

the first accurate description of small-pox, and the first treatise on the diseases of children; of Harvey, of Sydenham, Bonetus, Baglivi, and others, all of whom have secured their great renown by contributing to science and humanity some fact or facts secured by persevering labor and observation. Dr. Kemp had himself tested the accuracy of the prognoses of Hippocrates, and had been profoundly impressed with their sagacity. Locke and Bacon contributed powerfully to the independence of medical thought and investigation which characterizes modern times. Cullen and Morgagni, in the eighteenth century, the first in Scotland the second in Italy, continued with zeal and success the methods which had so crowned the labors of their great predecessors. The address continued at length to outline the methods and motives which should characterize the true student of nature and of science in the pursuit of knowledge. At its conclusion the address was appropriately referred.

The resignation of Dr. W. W. Murray, who has removed to Virginia, was read and accepted.

TREASURER'S REPORT.

The report of the Treasurer was read, showing a net gain of two members. There had been seven resignations, four deaths, and four dropped for non-payment of dues. Sixteen active and one honorary member (Dr. A. M. Fauntleroy, of Virginia) had been added. The receipts had been \$2,274, the disbursements \$1,736, leaving a balance in the treasury of \$538. The estimated increase in the value of the library was \$800.

The assets amount to \$9,125 (including library furniture, etc., valued at \$8,300). The society is free of debt.

REPORTS OF COMMITTEES.

The Publication Committee reported the distribution, in this country and abroad, of five hundred copies of the last volume of Transactions. The Committee on Memoirs announced, with appropriate allusion, the deaths of Drs. Wilson G. Register, the late Secretary; Charles Albert, Henry Albers, and E. Cleveland Cox.

The Committee on the Library reported gratifying progress in the condition of the library, constituting it the most valuable feature of the Faculty. It now contains 3,346 volumes, an increase of 277 during the year. Among the most valuable contributions are Ziemssen's "Cyclopædia," Sydenham Society publications to end of 1881, and many late editions of leading text-books. Number of books donated by members, 151; expenses, \$595.

One hundred and eight American and foreign journals are regularly received; a number of portraits of eminent Marylanders, including that of Dr. Upton Scot, of Annapolis, the first president of the society; a portrait and autograph letter from Pasteur; a medical diploma granted in 1769, to Dr. Josias Carvil Hall, of Maryland, by the College of Medicine, of Philadelphia, and other articles of value and antiquarian interest had been received. In concluding, the report recommended the adoption of a resolution authorizing the committee to exchange books and pamphlets with the Surgeon-General's library, in Washington, upon such terms as would promote the interests of the society. The resolution was adopted.

These reports, and others which present no general interest, were all accepted.

DELEGATES.

The following delegates presented their credentials and were admitted to seats: Dr. John H. Patterson, Baltimore Academy of Medicine; Dr. A. A. Hanna, Cecil County Medical Society; Dr. Walter Wyman, Chirurgical Society of Maryland; Dr. J. T. King, Baltimore Medical Association. Dr. Randolph Winslow (who leaves for Europe in the morning) was appointed a delegate to the International Medical Congress, which meets in Copenhagen next August.

THE REPORT ON ABDOMINAL SURGERY.

The Chairman of the Section, Dr. O. J. Coskery announced that the subject of his report would be Abdominal Surgery exclusive of operations in gynecological practice. He treated of gastrostomy, splenectomy, and nephrectomy. Gastrostomy, or opening the stomach for the removal of foreign bodies, or on account of obstruction in the œsophagus produced by simple or malignant strictures, has been made most successful since Mr. Howse suggested that the process should be divided into two separate stages—the first consisting of opening the abdominal walls and stitching the stomach to it by six or eight sutures; the second, opening the stomach itself five or more days afterward.

WHEN IS GASTROSTOMY JUSTIFIABLE.

After reviewing the cases reported and the statistics of the operation, Dr. Coskery concludes:

I. Gastrostomy is justifiable (A) in cases where a foreign body has been introduced into the stomach, which, owing to size or shape, cannot pass through the pylorus, (B), in cases where malignant contraction or diseases of the œsophagus is progressing. (C), where the disease in the calibre of the gullet is due to inflammatory action following the introduction of corrosive liquids, and where such contraction will not yield to the bougie treatment.

II. Under all circumstances the first possible opportunity for the operation should be availed of. Mr. Bryant, alluding to cases in which decrease in the size of gullet is the occasion for the operation, says, "Do it as soon as there is any difficulty in swallowing solid food."

III. The incision in the stomach itself should not be longer than one-eighth inch, unless made for the removal of foreign body, and then as small as will permit of its extraction.

IV. The operation is most successful ultimately when undertaken for the removal of foreign bodies or for accidental stricture of the gullet.

V. When done for obstruction to the swallowing of food, the operation should be divided into two stages, as was suggested by Mr. Howse.

THE INDICATIONS FOR SPLENECTOMY.

In regard to splenectomy, Dr. Coskery's conclusions were that the operation of splenectomy for conditions unassociated with leucocythæmia is pre-eminently the most successful in abdominal surgery, but when the white cells are very abundant in the blood, it probably is the most dangerous of operations and should be abandoned. The tendency to hemorrhage in this condition may alone be regarded as a barrier to the operation, even in the incipency of the disease.

The following are the conclusions reached by Dr. Coskery in regard to nephrectomy: The operation must be regarded as a justifiable one; the great difficulty lies in making a correct diagnosis between those conditions of the kidney requiring extirpation, simple tapping, or cutting down and extracting a stone from the pelvis of the kidney.

By the incision made in the same direction as for lumbar colotomy the operation should be as bloodless and as free from danger. The principal dangers are accidental adhesions and the shock of the operation.

SECTION ON PRACTICE OF MEDICINE.

DR. R. H. THOMAS read the report of the Section. His paper was entitled

A CONTRIBUTION ON THE INFLUENCE OF SEASON AND WEATHER ON THE DEATH-RATE FROM DIPHTHERIA IN BALTIMORE, 1861-1882.

The paper was freely illustrated by charts, showing the range of temperature, moisture, wind, etc., during the four and one-fourth years embraced by the report.

Dr. Thomas said that his study of these charts seemed to warrant the following conclusions:

First.—While the weather alone does not regulate the

absolute number of deaths from diphtheria, it has a very important bearing upon the rise and fall of the violence of the disease, although temporary fluctuations occur independently of it.

Second.—Temporary changes in the weather have but little effect; but a continued prevalence of certain kinds of weather does cause a rise or fall in the mortality from diphtheria.

Third.—The conditions favorable to arise are low barometer, low winds, especially from the East, high temperature with high humidity and heavy or continued rainfall.

Fourth.—The conditions favorable to a fall are high winds, especially from the West, low humidity, with high temperature, or high humidity with low temperature, and "generally" a high barometer.

SECOND DAY—APRIL 25TH.

The session opened with a report from

THE SECTION ON MATERIA MEDICA AND THERAPUTICS

read by DR. BARTON BRUNE, consisting of a *résumé* of the contributions made in urinary chemistry during the year. Dr. Brune paid especial attention to the recent lectures by Alfred Barring Garrod, of London, on uric acid and allied subjects, to various urinary pigments lately described, and to new tests for albumen and sugar, particularly the picric acid test of George Johnston, which he thought was likely to supersede the test now in vogue.

The report of the Section on Anatomy and Physiology consisted of a paper on

THE PROGRESS OF PHYSIOLOGY DURING THE YEAR,

by DR. LATIMER, which, owing to the author's being called away from the city, was read by title only.

The Committee on Sanitary Science reported through DR. J. R. WARD, President of the Maryland State Board of Health. The principal point in Dr. Ward's address was the stress which he laid upon

SANITARY INSTRUCTION IN THE YOUNG.

He urged that it should be made one of the subjects taught in the public schools. The susceptible minds of the young men were particularly adapted to receive and retain such instruction, which might then be spread broadcast through the masses.

The report of the Section on Ophthalmology, Otology, and Laryngology was presented by Drs. Friedenwald and H. Clinton McSherry. The former took for his subject

THE RELATIONS OF SPINAL AND EYE DISEASES.

DR. McSHERRY read a paper on

LARYNGEAL STENOSIS,

and exhibited an instrument designed to effect dilatation of the glottis from below after tracheotomy. It consists of three blades, by which dilatation is effected both laterally and antero-posteriorly.

Dr. McSherry reported three cases successfully treated by himself, and exhibited one of the three, who, after being obliged to wear the tracheal tube for a year, is now able to breathe freely without it.

The next was a volunteer paper by DR. C. W. CHANCELLOR, Secretary of the Maryland State Board of Health, upon

THE SEWERAGE OF CITIES BY THE PNEUMATIC PLAN.

This paper was based upon observations made in Europe by the author, who has recently been abroad studying the various sewerage systems in vogue. Dr. Chancellor discussed at length the relative merits of the various methods and expressed a very decided preference for the pneumatic system, which prevails in Holland. He urged the special adaptability of this system to Baltimore.

(To be continued.)

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 23, 1883.

DAVID WEBSTER, M.D., PRESIDENT, IN THE CHAIR.

DR. D. B. ST. JOHN ROOSA read an elaborate paper on

THE EFFECTS OF NOISE UPON DISEASED AND HEALTHY EARS.

The author first referred to the literature of the subject as found in the writings of Willis, Wilde, Kramer, Troltsch, Rau, Ficlitz, Burnett, and E. E. Holt, who published his paper in 1882. Politzer, and others. Willis, a little more than two hundred years ago, gave an account of a somewhat famous woman who could only hear the voice of her husband when a servant was beating a drum in the same room. The facts, as stated by that old author, have since been denied and affirmed, and differences of opinion have existed concerning the explanation of the phenomenon, of hearing better in a noise, when its existence has been admitted. Dr. Roosa showed subsequently that Wilde was in error in supposing that the phenomenon depended upon the state of the membrana tympani, and therefore could not occur when there was a hole in the drum-head. He did not agree with Troltsch that the symptom of hearing better in a noise was not a common one. His experience had proved that it is a very frequent one. Holt doubts if in any case the hearing-power is improved by noise. Politzer has no doubt as to the existence of these cases, and confirms what Dr. Roosa stated years ago, "that the patients can understand speech during such noises much easier and at a much greater distance than people with normal hearing;" but he (Politzer) has observed this symptom "almost exclusively in the incurable forms of affections of the middle-ear." Dr. Roosa believed that while the symptom frequently accompanied incurable disease of the middle-ear, it is a very frequent symptom in subacute cases, when both ears are affected. He had never seen the symptom except in disease of the middle-ear. He believed it never occurred except in cases where the nerve is sound. If it be true that it never occurs with disease of the acoustic nerve, the theory of an extraordinary excitement of the nervous apparatus, as a cause of the phenomenon, must be rejected. Special reference was then made to Politzer's explanation and to the conclusions reached in Dr. Holt's paper. Reference was then made to illustrative cases.

But there is a class of patients who have been made deaf by noise. They are often confounded with those whose impairment of hearing has resulted from catarrh, but are to be entirely disassociated from them. Boiler-makers, and those who become deaf from an exposure to the continuous shock of loud sounds, suffer from a lesion of the acoustic nerve. These patients hear better away from the din, and have a sense of relief when in quiet places.

The author of the paper then explained how, by the publication of certain views, he assisted in creating confusion in our ideas, as to hearing better in a noise and the effects of noise upon the ear. He then explained, by means of a diagram upon the blackboard, what is understood by bone-conduction and aerial conduction. This was followed by illustrative cases of boiler-makers' deafness.

The following conclusions were reached:

First.—There is quite a large class of people suffering from impairment of hearing in ordinary places who hear very acutely and with comfort amid a great din or noise.

Second.—The disease causing the impairment of hearing thus relieved, is situated in the middle ear. It has been usually observed in the chronic non-suppurative

form of disease of the middle ear, but it may also be found in acute and subacute catarrh of this part, as well as in the chronic suppurative process.

Third.—The proximate cause of this phenomenon is not as yet positively known. It is probably to be found in some change in the action of morbid articulation of the stapes bone with the fenestra ovalis.

Fourth.—The hearing-power of persons working in such a din as that of a boiler-shop invariably becomes impaired.

Fifth.—The lesion caused by this occupation is one of the labyrinth, or of the trunk of the acoustic nerve.

Sixth.—Persons thus affected do not hear better in a noise. Their hearing-power is better in a quiet place, and becomes better after prolonged absence from the exciting cause of their impaired hearing.

Seventh.—The cases of inspissated cerumen and catarrh of the middle ear, occurring among boiler-makers, are such as occur among those engaged in other occupations, and mask and complicate the fundamental primary trouble so long known as boiler-makers' deafness.

Eighth.—In disease of the labyrinth or acoustic nerve the tuning-fork "C" is heard louder and longer through the air than through the bones of the head.

The President invited DR. KNAPP to open the discussion, who said that the paper was so much in the direction of new experimentation, and observations which must needs be repeated in order to discuss the subject properly, that he had nothing to offer. So far, however, as his observation had extended upon this question, it agreed in the main with Dr. Roosa's, although he could not entirely agree with him in reference to distinguishing between internal and middle-ear disease.

DR. BRANDEIS said that the experiments which he had made had led him well toward the conclusion to which Dr. Roosa had arrived. At the time Dr. Holt read his paper Dr. Brandeis ventured to take issue with him, and claim that in boiler-makers' deafness the disease was not of the internal ear, but in a majority of cases was an affection of the naso-pharynx which extended to the middle ear and tympanic cavity through the Eustachian tube, and that the impairment of hearing was not due so much to impairment of the integrity of the nerve as to the ankylosis of the ossicles and closure of the Eustachian tube. He had found very great difficulty in determining exactly the amount of impairment of hearing in boiler-makers; also, whether it was due to impairment of the integrity of the auditory nerve or of the conducting apparatus, because in every one of the cases there was decided naso-pharyngeal and Eustachian catarrh. In many cases he was inclined to believe that the catarrhal condition was the principal factor in the etiology of the deafness. Dr. Brandeis had recently observed a number of cases of unilateral impairment of hearing, especially among violinists. Here again he was inclined to the opinion that the difficulty was not alone in the internal ear, but that there was also a simultaneous affection of the middle ear, the tympanic cavity, and the ossicles, which he attributed to partial compression of the arteries that go to supply the middle ear, thus impairing the circulation.

DR. POMEROY was inclined to place considerable stress upon the observations made by Dr. Holt, who with others had demonstrated beyond question that there is middle-ear disease in a very large number of these cases of boiler-makers' deafness. Dr. Pomeroy believed that the appearance of the membrana tympani generally sustained that proposition. In many cases it is altogether opaque, showing the signs of a considerably long continued low grade of inflammation, resulting in a certain amount of proliferation. Moreover, all the men who are thrown into the category of boiler-makers are especially exposed to those causes which are supposed to give rise to catarrh. That there is actually catarrh present in a very large number of cases he thought was admitted by all observers. At the very beginning, then, a condition was present which

served to render diagnosis difficult. Dr. Pomeroy's belief was that it begins as a middle-ear trouble and travels into the labyrinth. With regard to the tuning-fork furnishing evidence of middle-ear disease, that is a question requiring the utmost acuteness of observation. Our knowledge on that subject is still so defective that all statements made with reference to it must be taken with a great deal of allowance. He was sure the statement, that if a patient hears the tuning-fork louder and longer by aerial-conduction than by bone-conduction he has not middle-ear disease, but labyrinthian trouble, was true in only a certain number of instances. With regard to hearing better in noise, he believed that in a large number of instances patients with middle-ear trouble were likely to hear better in a noise than a person with normal hearing, and better than when in a quiet place. But that fact he thought was not sufficiently important to be of special diagnostic value. A person may have middle-ear trouble and not hear better in a noise.

DR. BACON believed with Dr. Roosa that the real difficulty in boiler-makers' deafness is in the internal ear. At the same time the middle ear is, in the majority of cases, affected with catarrhal troubles.

DR. ANDREWS said that, at one time, he studied this subject carefully for a number of years. Inasmuch as there had been no post-mortem examinations to verify the statements given this evening, it would be impossible, he thought, to positively locate the disease. Disease of the middle-ear might give all the evidence of disease of the labyrinth, and yet the labyrinth be perfectly normal. He believed that we could not yet, in these cases, positively locate the disease in the labyrinth so long as tympanic disease cannot be eliminated as an acting cause. Dr. Andrews thought that the absence of the drum-head, referred to by Dr. Roosa as disposing of Wilde's explanation, did not dispose of the view entertained by Wilde, inasmuch as the round and oval windows were probably intact.

DR. ROOSA, in reply to Dr. Andrews's question, said he supposed the two windows were intact. But he believed that their presence did not overthrow the argument, because Wilde held that the phenomenon depends upon relaxation of the drum-head; whereas he (Roosa) believes that it depends upon some change of the ossicles, a decidedly different condition.

Dr. Roosa could not agree with Dr. Andrews in the broad statement, that because no post-mortems had been obtained in cases of boiler-makers' deafness, therefore we cannot ever tell whether we have to deal with disease of the middle-ear or of the internal ear. He had assumed two things which he expected would be doubted, and they had been doubted; but he did not think that they had been disproved. He had the fortune of being a pioneer in this kind of investigation, and had come to believe that in the tuning-fork we have a means of making a differential diagnosis between disease of the middle and internal ear. Hearing better in a noise was another means, and by employing these two aids he believed that a differential diagnosis in these cases could be satisfactorily made. Practice in ear diseases had gone to extremes. Only a few years ago nearly every otologist followed Kramer, who said that the acoustic nerve was the part most commonly affected; then Wilde, who said that disease of the middle-ear explained all the symptoms; later the Germans, who came with catarrh of the middle-ear and swallowed all previous theories. Now, no matter what the ear affection may be, the organ must be blowed up almost invariably, according to some authorities, and their teaching is practised by a large number of otologists. Dr. Roosa was contending against that view, and was trying to prove that there is quite a large proportion of cases of deafness in every vicinity, due to acoustic trouble, which are incurable, and that it is better to let them alone than to be continually blowing them up with an apparatus.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 19, 1883.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

DR. GASPAR GRISWOLD read a short paper on

CRYSTALLINE ELATERIN.

The author of the paper first spoke of the excellency of elaterium as a hydragogue cathartic, and referred to the uncertainty in obtaining desired results, because of the variations in the strength of the drug sold in the shops. He then described the methods by which the crystals, the active principle of the juice of the cucumber, should be obtained in order to be reliable, and exhibited specimens which illustrated the differences in appearance between the inert substance and the white hexagonal crystals known as elaterin. The following conclusions were reached: First, that the crystalline elaterin of Merck, now for sale in this city, is identical with that discovered by Morries in 1831, and is the active principle of elaterium; second, that its distinct crystalline form and freedom from impurity renders it more reliable than any preparation of elaterium; third, that the proper dose to commence with is one-tenth of a grain, and that this may be prescribed in a solution of one grain of elaterin to half an ounce of alcohol, or in the form of tablet triturates, containing one-tenth of a grain. The last are now to be had at Frazer & Co.'s pharmacy.

ANTEFLEXION OF THE UTERUS—ITS ETIOLOGY AND ASSOCIATED PATHOLOGICAL CONDITIONS.

DR. W. GILL WYLIE read a paper on the above subject, in which he first directed attention to the anatomy of the position and surroundings of the healthy uterus. This referred to the shape and size of the organ, its depth, flexibility, etc. The average depth was given as a little over two and one-half inches. When pressure is made on the fundus or upper portion, the organ bends, chiefly at the os internum. It does not bend so as to form an acute angle, but with a curve such as would be made by a rubber tube with very thick walls and small calibre. In very rare cases the anterior wall might be bent at a much more acute angle. A description of the supports of the uterus was then given. It is held in position chiefly by the fasciæ and connective tissue of the pelvis, and by the reflexions of the peritoneum. These form more or less distinct ligaments, in which there is more or less muscular tissue, and are so elastic as to permit considerable mobility of the uterus as a whole, especially upward and downward, and backward and forward.

The elastic contractility of the muscles and connective tissue, that is, the heart and muscles of the arteries, muscles of the ligaments and perineum and abdomen, the connective tissue of the skin and the abdomen and perineal walls, of the ligaments, fasciæ, and so-called cellular tissue of the pelvis, unitedly exerted a pressure to which he gave the name *vital musculo-connective-tissue pressure*.

Dr. Wylie then proceeded to the consideration of the dynamics of the pelvic cavity, or the influence of force in causing antelexion. The influence of atmospheric pressure has but little to do with keeping the pelvic organs in place by opposing gravity. In order that this force may act as a retentive power by counteracting gravity, the vessel must be rigid and fixed above as well as on the sides, and impermeable to air. Gravity acts upon the contents of the pelvis as it does upon the semi-solid, elastic, and mobile contents of a rigid cylinder with a flexible bottom, and with a top opening into another flexible cylinder, also filled with an elastic ever-changing mass, falling and lifting at all times, and with more or less force.

The writer then spoke of the influences which prevent

a normal uterus from bending forward at or above its middle when the person stands erect, or when it is pressed upon by the action of the diaphragm and abdominal muscles, etc. First, the firm, elastic nature of the tissues of the organ had a tendency to keep it in its normal shape; second, the forward inclination and slight anterior curvature of the normal uterus placed the organ in the best possible position to enable it to withstand both continued and sudden waves of force from the action of the diaphragm and abdominal muscles. The third influence mentioned was the vital musculo-connective-tissue pressure—that is, the sustaining power of the surrounding flexible and elastic adjustable tissues, which during life are filled with blood, fluids, gases, etc. So important is this influence that it cannot be left out when considering the dynamics of the pelvic cavity, and while the uterus is surrounded by these elastic and adjustable tissues in the living body, it is sustained in the same way as a flexible sea-weed is when surrounded by water. In other words, the tendency of the fundus to fall forward and bend the uterus on itself is very much less than it would be out of the pelvis.

The advocates of the mechanical pathology of uterine displacements had overlooked this greatly modifying influence of all indirect force acting on the pelvic organs, and had, therefore, exaggerated the effects of sudden falls in producing antelexion, consequently were naturally led to rely too much upon mechanical support for effecting a cure. The effect of downward pressure on the healthy uterus tends to produce general prolapsus rather than antelexion.

Dr. Wylie then asked the question: When a uterus is soft what causes it to become flexed when the person is erect, or when there is downward pressure produced by the action of the diaphragm and abdominal muscles? The answers were, first, the normal position of the uterus is one of anterior curvature, and if the tissues are soft the weight of the fundus has a tendency to increase this curvature; second, downward pressure would cause the pouch of Douglas and the bladder to yield first, and this yielding would make taut the utero-sacral ligaments attached to the uterus just above the vaginal junction posteriorly until these ligaments gave way. This particular part of the uterus would be held upward and backward, while the abnormally soft cervix would be pushed downward in the direction of the vaginal axis. At the same time the utero-vesical ligament would be made taut only at its higher points of attachment to the uterus, and the upper part of the fundus would be pulled downward on the bladder. The third answer referred to Hart's views as to the floor of the pelvis being divided into two segments, the author accepting some of them with modifications. Fourth, the loss, to a greater or less extent, of the vital musculo-connective-tissue pressure. Dr. Wylie then spoke of the influence of downward pressure in producing backward and forward displacements of the uterus, the latter result being the most frequent and the most important pathologically.

The influence of the bladder on the position of the uterus, and the influence of the rectum on the uterus were then considered.

The point of greatest curvature in antelexion was mentioned next, and the writer stated that the exact location of this point is often very difficult to determine. As a rule, it is just about the os internum. And he then gave the reasons why it occurred at this point.

The time of making examinations to decide the exact degree of flexion should be carefully considered; for, without doubt, the amount of curvature varies at different times, for instance, just before and just after menstruation. The most favorable time is during one or two weeks between the menstrual periods, when the uterus is usually quiescent.

After speaking of the variability of the generative organs reference was made to the frequency and degree of antelexion. All nulliparous women have some degree

of anterior curvature of the uterus, and this may vary considerably without denoting an abnormal condition; that is, while the uterus is quiescent the angle made by the axis of the cervical canal with the axis of the canal of the body may vary from 165° to 135° without being abnormal. But when it is most of the time found less than 135° it may fairly be called abnormal.

ETIOLOGY.

Under this head the author considered the influences which prevent the perfect development of the organs of generation; the enervating influences of modern life; the general tendency to development of the intellectual faculties at the expense of the physical health; the tendency there is in civilized communities to keep the function of these organs under restraint, enforced restraint brought about by measures to avoid child-bearing; the influence of deformities of the pelvis; the influence of excessive physical labor, although not so potent as excessive intellectual development, etc. The condition of the general health has much influence on the development and position of the uterus. Many of the cases classed as congenital are undoubtedly merely flexions made permanent before maturity is reached. Of children born of healthy parents, few reach full development in perfect health.

In those who have an inherited or acquired rheumatic diathesis, or a tendency to catarrhal diseases, exposure to malarial poisoning or to cold may induce endometritis, and finally lead to anterior displacement.

Child-bearing is usually enumerated as a predisposing cause of antelexion; but Dr. Wylie preferred to say that too frequent child-bearing, or abnormal labors or the puerperal state, or labor in an unhealthy woman, may result in an antelexion. Child-bearing is as truly a natural act as is eating. Besides these, a large number of causes were mentioned.

PATHOLOGY.

For several years past he had given up the belief that antelexion very often directly caused dysmenorrhœa by mechanically closing the canal, and thus obstructing the menstrual flow. Where there is obstructive dysmenorrhœa, except in rare instances, he believed it to be due, as a rule, to stenosis of the os uteri at some point, or to clonic spasm at the os internum, as is the case in the majority of instances of dysmenorrhœa in antelexion. He believed that pain and obstruction is caused by the hyperæsthetic condition at or near the os internum, combined with more or less stenosis at this point.

Antelexions may be divided into two classes: first, those usually termed congenital, that is, those in which the curvature exists before puberty, or is acquired before maturity is completed, and the result of interfered or imperfect development; second, those in which the curvature takes place after full growth. The peculiarities of these two classes of cases were then discussed at some length.

The President invited DR. T. ADDIS EMMET to open the discussion, who thought the subject could be simplified by recognizing the fact that in most cases the condition under consideration is due entirely to obstruction of the circulation outside of the uterus. As a rule, it is due to inflammatory action caused by cold. When we have dysmenorrhœa accompanied with that condition it is not a mechanical affection, but it is due to faulty nutrition and obstruction of the circulation, and is an affection of the general system. He believed that it was very important to recognize this as a cause of flexure from the simple fact that malpractice was seen to no greater degree than in the treatment of such conditions by dividing the cervix, dilating the canal, etc., etc., treating the effect as if it were the cause. Inflammation in the pelvis somewhere, in one of the ligaments, is the chief cause of antelexion, and this explains why we have so uniformly

trouble from surgical procedure for its relief. If attempts are made to raise the uterus before the pelvic inflammation is removed, a fresh attack will be set up. This doctrine is applicable to the treatment of all versions, and it is due to this fact that there is such a difference of opinion in regard to the use of pessaries in the treatment of uterine displacements. Whenever we treat anteversions and reduce inflammation to a point at which it is regarded as safe to undertake to restore the uterus to its normal position, whatever the mechanical appliance is that is employed, it simply relieves the patient by raising the organ up to where the circulation can be restored; sometimes we can antevert the uterus still more than it is anteverted, and yet give entire relief. The principle is not simply to correct the position of the uterus so far as flexion or version is concerned, but to raise the organ up in the pelvis to a point at which circulation can go on unimpeded.

DR. W. T. LUSK said he had been invited to participate in the discussion; but inasmuch as the author of the paper had anticipated nearly all that he had proposed to say, he would not further consume the time of the Academy.

DR. W. M. CHAMBERLAIN thought the paper covered a range of inquiry which all would do well to prosecute. He referred to a single illustration of one point, namely, the propagation of force from the contraction of the diaphragm and connective-tissue movements in the upper part of the abdomen. Whoever has had occasion to watch the movements of the pelvic viscera in a patient anesthetized for operation, and has noticed the result when an attack of vomiting came on, would recognize the fact so well brought out, that the maximum downward pressure is not exerted into Douglas' cul-de-sac, but into the space anterior to the uterus and upon the posterior wall of the bladder. So far as his observation went, the extrusion of the vaginal wall had always been much more in the form of a cystocele than in the form of a rectocele.

The dynamics of uterine movement has a wide relation to education and habits as well as to the cure of the sick, and he thought that manifestly any great departure from the order of nature, as is frequently dictated by fashion, was likely to be mischievous. For example, the influence of affected posture, what is sometimes called the "Boston tip," in which the body is bent forward and the abdominal walls are relaxed, he believed was prejudicial to good health. The influence of high-heeled boots he also believed was a factor worthy of consideration. He was especially pleased with Dr. Wylie's statement concerning the influence of the vital musculo-connective-tissue pressure. While Dr. Emmet had spoken most judiciously of antelexions depending upon a greater or less amount of pelvic inflammation, he thought there were antelexions, but more especially anteversions, which are the source of great discomfort, which never can be cured by any mechanical appliances, because they depend essentially upon an empty state of the connective tissue. And he believed that in many of those women who are bedridden, the displacement continues because they are bedridden, and that the one means of restoring them is to restore the normal condition of the connective-tissue system.

DR. WYLIE, in closing the discussion, said, with reference to Dr. Chamberlain's remark, concerning the effect of pressure of the diaphragm being chiefly expended upon the bladder when the patient was anesthetized and placed in Sims' position, that Dr. C. would recollect that in Sims' position the curve of the spine is mainly taken out, and that the greater part of the force is directed downward more in the direct line of the bladder. In the upright position he thought that the pressure was so equally distributed that there is a proper balance between the two, and that the uterus settles in the pelvic cavity in accordance with this equalized and balanced pressure.

DISCUSSION ON THE NEW CODE, AND WHAT CAME OF IT.

The Academy then proceeded to the transaction of new business.

DR. AUSTIN FLINT, JR., rose and said: I have been requested to introduce a certain preamble and resolutions with reference to the election of resident Fellows. I think, Mr. President, it is time that in this hall, the gift of a distinguished fellow and benefactor of this Academy, in the presence of these portraits of past presidents and distinguished fellows, and many good men who have left us, I think it is time that resolutions should be introduced deprecating the admission of any Fellow who cannot conscientiously sign, as we have all signed, and cannot cordially support, as we should all support, the Code of Medical Ethics recognized by the regular profession of this city, State, and country, the Code of Ethics which has been embodied as one of the by-laws of this Academy. I therefore move you, Mr. President, the adoption of the preamble and resolutions which I will read:

Whereas, The New York Academy of Medicine has adopted in its By-Laws, and as its standard of medical ethics, the Code of Ethics of the American Medical Association; and

Whereas, Each newly elected Fellow of the Academy is required to sign its Constitution and By-Laws, be it

Resolved, That the Committee on Admissions be and are hereby instructed to report to the Academy for election as resident Fellow, no physician who is known by the Committee to be in opposition to the Code of Ethics of the Academy, and who in consequence cannot conscientiously sign the By-Laws of the Academy; and

Resolved, That these instructions to the Committee on Admissions continue in force until the American Medical Association shall have modified or repealed its Code of Ethics, and such modification or repeal shall have been adopted by the Academy, or until the Academy shall have modified or repealed its by-law referring to medical ethics.

DR. J. P. GARRISH.—I second the resolutions.

DR. C. R. AGNEW.—Mr. President: Of course, in common with a large number of my colleagues and Fellows of this Academy, I have had no intimation of the import of these resolutions offered at this time. It was only by accident, the merest accident, that, at half-past seven o'clock this evening, I heard that a certain number of the Fellows had been secretly informed that such resolutions would be introduced. It seemed to me, when informed of the intention of my honored colleague to introduce such resolutions—accidentally and unintentionally informed—that I had a right to suppose, as a Fellow of this Academy, I should have been informed by the Secretary of the Academy of the intention to introduce resolutions of this kind. It has been very evident, by the rhetorical way in which our distinguished colleague has introduced them, that these resolutions have been well prepared, and that persons have been informed that they were to be introduced, and so a very large attendance at the Academy has been secured of those who were known to be favorable in advance to the ethics of the resolutions which the gentleman has introduced.

Now, may I ask the Secretary to read the qualifications for membership in this Academy? These are found in the Constitution, Article 3, Section 1.

The SECRETARY reads: "Each candidate for Resident Fellowship must have been a graduate or licentiate in medicine residing in this city and county, or in either of the counties of this State thereunto adjoining, for three years."

DR. AGNEW.—Are there any other qualifications provided for in the Constitution, Mr. President, for admission into this Academy?

THE PRESIDENT.—Signing the Constitution and By-Laws.

DR. AGNEW.—Then it seems to me that it is the in-

tention of the resolutions to embody in the Constitution of the Academy an additional qualification for membership, and that it should have been noticed by the Secretary in conformity with the provision of the Constitution, which says that "no part of the Constitution shall be altered, except at a stated meeting, subsequent to one at which a proposition to that effect shall have been made in writing, and then only by a vote of three-fourths of the Resident Fellows present."

Now I move that the resolutions with their preamble be laid upon the table until that provision of the Constitution shall have been complied with. It is proposed to establish a new test for membership, and I think the Secretary should, in conformity with the custom of the Academy, if nothing more, give notice of their introduction. I call for the Ayes and Nays on my motion.

Ayes 32. Nays 60.

The motion to lay on the table was declared lost.

DR. ROOSA.—Mr. President, the distinguished gentleman upon this occasion seems to have forgotten the scene which occurred in this Academy when his even more distinguished father, in an address to the medical profession, counselling harmony, distinctly stated that it was in the County Medical Society that discussions like this were to be carried on, and that, that was the arena for the discussion of ethical subjects on which medical men of all shades of opinion might differ. It is very interesting to watch the indignation beginning in Brooklyn and being continued in Philadelphia, which it has taken a year and a half to whoop up to proper dimensions. When the Medical Society of the State of New York, in the right given to it by a charter as old as 1809, and given to it by its by-laws, which have not been repealed, did in 1882 repeal a certain section of its by-laws, I had the honor of conversing with many of the gentlemen who have now become so excited lest the honor of the profession of the State should be entirely swept away, and I failed to see then any of the indignation expressed in the gentleman's remarks when he claims that he and his party alone represent the regular profession, and causes the inference that those gentlemen who do not resort to the same expedients to obtain control of medical societies, represent an irregular profession. This is not a spontaneous agitation. It is not an expression of the real sense of the medical profession lest its time-honored rules should be overturned. It is an expression created simply by a secret society, a high organization which sends its orders to individuals to be present on certain occasions. This is an agitation which is all artificial, and is one of the most decidedly political organizations which ever existed.

It was not until this evening at a very late hour that we became aware, those of us who are standing by the rights of the medical profession of the State of New York [Interruptions and jeers, promptly suppressed by the President], and of that society which will survive any derision, and can rest secure simply upon its own history and its own merits, it was only at a late hour, I repeat, that we knew anything of such an occasion as this, or we should have been better represented than it has been our fortune to have been. If there were that sublime ethical feeling for which these gentlemen are clamoring, even if any attention had been paid to that law of ethics, higher than those of any academy or any American medical association, to the law which obtains among men who are waged in contest with each other, we would have been notified that this matter would be brought up to-night, and it would not have appeared in the characteristic method in which it has been presented. To properly characterize it would require language not parliamentary, and from which I will refrain. I simply appeal to the honor of the gentlemen who differ with us in opinion concerning ethical interpretations, and who claim to represent the purity of the ethics of the profession, as against us who are irregular.

DR. GOULEY.—I rise to a point of order. The gentleman is not speaking to the question.

THE PRESIDENT.—The Chair decides that the gentleman is speaking to the question.

DR. ROOSA.—I wish simply to say that I appeal to the honor of the gentlemen who claim to represent the purity of the ethics of the profession, as against us who are irregular, that they shall forego their action this night, and allow us to discuss this question when the Academy may have a fuller representation. I trust I see men here, no matter what their obligations upon the general question are, who are under no obligations which would bind them to disregard the common courtesies of any contest, and especially this one, which thus far has mainly been carried on in a friendly way. I hope it will be continued in a friendly manner, and let us at least have an opportunity to say what we may have to say when we are adequately represented.

THE PRESIDENT.—The Chair begs leave to state that any one speaking on either side, will, while he is speaking, be protected, and that without reference to the opinion he may express.

DR. FLINT, JR.—Mr. President, I would like to explain with reference to certain strictures which have been made by the gentlemen who have spoken. All I intended to say was in the few remarks with which I introduced these resolutions, and they constituted all which I should have said upon the subject, did I not feel that I must reply to the strictures which have been put upon me and have been put upon some others. We consulted together, and all thought it best that these resolutions should be introduced at this time. They have no reference to State or county medical societies. The movement which many of us have gone into is to sustain the Code of Ethics of the American Medical Association until it shall be modified by that body.

The New York Academy of Medicine is the only chartered medical society in the State of New York, which is entitled, through its delegates, to recognition, either in the American Medical Association or in any of the State Medical Societies in the Union. I wish that fact to stand fully before the mind of every Fellow of the Academy. Now the question is that, being the only body which can send delegates to the forthcoming meeting of the American Medical Association, that being disfranchised by an action which I shall not attempt to characterize, that action which cannot be compared to anything—I will not try to go on—but I think many of us feel deeply that that action has been the occasion of such action as we have taken to-night. It is true, we invited our friends to be present, and expected that they would be here and vote for these resolutions. But we have not organized and given our organization a public appearance in medical journals; but we have a list of the names of the men who have signified their willingness to sustain the Code of Ethics of the American Medical Association until it is so modified, which I will give to any one who may ask for a copy. There is no secrecy in the matter, but the simple question is this, Will the Academy take the ground which shall put it right before the country, before the medical societies of our sister States, and right before the American Medical Association?

Shall we fall in with the idea that there may be a code of ethics for New York State, another for New Jersey, another for Connecticut, another for Massachusetts, and so on? Shall we do it? Or shall we sustain the code which has governed all the States? I contend that we have a right to call our Committee on Admissions to account if they report for election any men who cannot sign these By-laws. It does not follow that they must be called upon to go and vote against good men on that account. But that committee should know their duty. We are not modifying the Constitution or By-laws, we are simply saying that it is the sense of this meeting, that these are the By-laws which are to be signed, and that they are to be signed without mental reservation. The Academy may dismiss the committee, if necessary, if it does not do its duty, by a two-thirds vote. If any one

feels that he is hampered by this action, he can resign. I have considered the matter carefully, and I undertake to say that there is no thought of any new qualification or modification, or alteration of the By-laws, but it is simply a resolution to instruct this committee to act in accordance with the By-laws. I hope it will pass, and I hope that this question regarding the Academy of Medicine will be forever settled.

DR. AGNEW.—As the gentleman says there is no organization on their part, I ask if he would have any objection to telling us the method by which he secured this attendance of his associates? [Confusion, and cries of order, question.]

DR. PURPLE.—Is that in order? Has the gentleman a right to call upon any member of this Academy to tell the mode in which he attempts to support the Constitution and By-laws of this Institution. We wish to let the profession know that this Academy has its code of ethics, and that it is not a dead letter. There are those members here to-night, gray in years, who have stood by this institution, stood by its Constitution and its By-laws, and they are going to go through thick and thin to support them, and if need be to fight for them, either by blackballing or any other means which will support the By-laws. The gentleman must not consider that these are dead letters. [Question, question.]

DR. WEIR.—If I understand Dr. Flint correctly, his resolutions are only intended to instruct the Committee on Admissions as to their duties; that they are not to do any more by passing these resolutions than is now expressed in the By-laws. Therefore I do not see why the passage of such resolutions should be enforced. We have no delegates to be sent to the American Medical Association. They have already been chosen. We have no meeting to-night in accordance with all fair working, and I think we are entitled to this consideration from gentlemen on the opposite side; that due notice should have been given, and that this matter should be postponed until the next meeting or to a special meeting. I am sure that is not much to ask of them.

DR. A. H. SMITH.—I should like to ask, before I vote on this question, inasmuch as everything seems to hang upon the intents and purposes of the candidate, how the members of the committee are to know what he is going to do, and exactly how the committee are to go about settling the question for his conscience—a question which should arise in the conscience of each man. It seems to me that it is rather ungracious, and that to clothe the committee with any such power is extending to it a province which does not belong to any committee. I would like to know upon what ground the action of the committee is to be based.

DR. IRA B. REID.—The object is to throw upon the committee the work which would be otherwise thrown upon all of us every time a name comes up. The By-laws and Constitution are not usually presented to the candidate to sign before his name is balloted upon, and it is simply to permit him to say whether he can sign them or not; if he cannot the matter is ended with the committee; if he says he can the committee will present his name for election.

DR. E. C. HARWOOD read Sec. 14, Art. 5 of the By-laws, which relates to the Code of Medical Ethics of the Academy, and said that when he entered the Academy he signed these by-laws and constitution, and that he proposed to stand by them, and it implied that he must stand by the Constitution and By-laws of the American Medical Association. At the same time he did not see any necessity for the resolutions that had been introduced, as the same ground had been entirely covered by the By-laws. He would be glad if the subject could be considered more fully, and what the opposite side had claimed he regarded as no more than fair. He had always sustained the Code of the Academy, but he did not see any necessity for the resolutions, and believed that they were entirely out of order, and declined to vote.

DR. PARTRIDGE said if the resolutions were a modification of the By-laws, a three-fourths vote would be required. Were they intended as such, or simply as instructions to the Committee on Admissions?

DR. AGNEW.—It is an aphorism of Montesquieu that any act of authority exercised over one man by another, which is not absolutely necessary, is tyranny. [Oh! Ho!] Now these gentlemen, who hope these resolutions will be adopted, imagine that this act will help their cause. I tell them that it will not. The cause of liberty of conscience [Oh! Oh!], which we represent, is a cause which is advocated by a higher power than that of man. The Medical Society of the State of New York appointed a committee to revise its system of medical ethics, that committee made its report—a report which was afterward adopted—and which was in strict conformity to the Statutes of the State of New York. The New York State Medical Society in so doing accomplished an act which cannot be overthrown as long as the people of this State are influenced by the principles of the love of freedom which animated our forefathers. [Derisive laughter.] Gentlemen may jeer and scoff and laugh in derision. So it was when Disraeli stood up in the House of Commons; he was laughed at by more respectable gentlemen than those who sneer at me, and gentlemen who represented the aristocracy of their profession. I am a much smaller man than Disraeli, but I tell my scoffing friend on my right—

DR. JOHN G. ADAMS.—I call the gentleman to order.

DR. AGNEW—that the time will come when this Academy will hear me. Now, Mr. President, the Revised Statutes of the State of New York—

DR. FLINT, JR.—Ah, we have heard enough about that.

DR. AGNEW.—Very well, if this Academy does not wish to hear me it can say so.

THE PRESIDENT.—The gentleman is in order and will proceed.

DR. AGNEW.—I was about to state that the Revised Statutes of the State of New York say that any incorporated society shall have its by-laws strictly within the limits of those statutes. The friends and advocates of the Code of Ethics of the State of New York did not come in to disturb this Academy. They had no intention of bringing this question into the Academy. I defy any man to bring evidence of any infraction by us of the Code of Ethics of the American Medical Association before the Medical Society of the State of New York passed its revised Code allowing consultations with legally qualified practitioners, and brought its by-laws to conform with the statutes of the State. We know gentlemen, however, in this Academy who have lived in violation of the Code of Ethics of the American Medical Association, and who would have to take refuge under the Code of Ethics of the Medical Society of the State of New York if their cases were carried before the Academy's Committee on Ethics. Now I had hoped that the gentlemen would consider the full bearing of the question before they passed these resolutions, and before bringing in here a disturbing element. The number of men who have voted in opposition to them, even under these unfavorable circumstances, shows that this Academy is not united. The number is sufficiently large to show that they cannot be disregarded and ignored. Matters of morals and matters of conscience should not be settled by a certain number of men who, organized like ku-klux, endeavor to compel others to submit to their will. [Cries of "Order, order, order."]

DR. ROOSA.—I ask for the ruling of the Chair: Does this measure require a majority or a two-thirds vote?

THE PRESIDENT.—The Chair decides that it is not a by-law, being simply a resolution containing instructions, and therefore only requires a majority to adopt.

Ayes, 56. Nays, 26.

THE PRESIDENT declared the resolution adopted.

DR. FLINT.—I move a reconsideration.

DR. GOULEY.—I move that the reconsideration be indefinitely postponed.

DR. AGNEW.—What is the object in postponing indefinitely? [Cries of "Order, order."] I simply ask the question if it is the intention of the gentleman to put this subject beyond further discussion?

DR. FLINT.—It is.

DR. AGNEW.—Then the object is to throttle this Academy?

DR. FLINT.—Undoubtedly it is.

DR. AGNEW.—I call for the privilege of having this statement recorded, that it is intended to throttle discussion in this Academy. [Cries of "Order, order." "Question, question."]

THE PRESIDENT.—The Chair, before putting the question, wishes to state that in his opinion no body, by any parliamentary move, can declare that expressions of opinion or action upon any question can never be changed by that body.

The motion to indefinitely postpone was carried.

DR. FLINT.—Mr. President, I have now another resolution to introduce, and I hope it will be adopted.

Resolved, That the Academy hereby disavows any sympathy with the action of the State Medical Society which has put the State and County Medical Societies in an attitude of opposition to the profession of the State through the State and County Societies.

DR. ROOSA.—Mr. President, it was agreed, as much as it can be agreed among gentlemen, that this fight would not be carried into this Academy, and now it has been brought here by means which no honorable man can successfully defend. [Cries of "Order, order."]

A motion was made to adjourn.

THE PRESIDENT.—I wish to make a request, and I beg the pleasure of the Academy to comply with this request. I beg that some gentleman will make a motion, which I believe most earnestly and most strongly should be adopted in the best interests of the Academy, and that is, that the by-laws be suspended, and that when the Academy adjourns, it adjourns to meet on the first Thursday in October. [Confusion.]

DR. WEIR.—Before that motion is made, Mr. President, I wish to make a statement. I believe I am called upon to choose between the law of the State and the State Medical Society, and the Code of Ethics of the American Medical Convention, an organization of which I know nothing. I consequently choose to abide by our State law and the Medical Society of the State of New York and therefore tender my resignation as Vice-President and Fellow of this Academy. [Confusion.]

The motion asked for by the President was made and put, and declared lost.

DR. E. D. HUDSON, JR.—I would like to know if intimidation has not been a part of the mode adopted by the friends of this organization which has such a following. To the best of my belief they have had their secret meetings in this building, with locked doors, where measures were discussed for packing the hall this evening to vote for these resolutions. [Great confusion.]

DR. WILLIAM T. WHITE.—As Chairman of the House Committee, I wish to say that I do not know of any such meeting.

DR. AGNEW.—I wish simply to raise my protest once more. It has always been the practice of this Academy to issue notices containing memoranda of the work proposed, and in that way every gentleman has had an opportunity to attend and act upon questions in which he was either especially or generally interested. In that respect the Academy has been on the side of the best kind of parliamentary practice. Now, this secret society which issued its instructions to its members some time or other during the last day or two, has prepared for the action of this Academy a resolution which contains the most important questions which this Society has ever undertaken to decide upon, and yet no notice of it has been given to the Academy in general. We might have come here simply supposing that papers were to be read, but a sufficient number have been gathered to accomplish

the purposes of the mover of these resolutions—resolutions duly prepared in ink and with facility of expression; and the direct voting which these men so assembled have given, shows how well they are drilled, and that each gentleman is under command. I simply wish to put in my protest, and to say that such a movement will not bring peace or honor into this Academy. One of the principles upon which this Academy is based is, that there should be toleration of dissent. Our profession has reached its eminence, I know, by doing things against precedent, but these gentlemen propose to enforce a system of ideas from which there shall be no dissent without incurring their displeasure. But I am not afraid of their displeasure. I see a gentleman pointing his finger at me. I defy him or any other man to bring any charges against me. In accord with my convictions, I defy these men who have organized this secret Society, and who have come here to throw this Academy into anarchy. If there is not to be freedom of discussion and freedom of opinion in a scientific body, where is there to be freedom?

DR. GIBNEY.—I move that, in the interest of harmony, the question be laid upon the table.

Lost.

The resolution was then adopted.

DR. FLINT.—I move a reconsideration.

DR. GOULEY.—I move that the reconsideration be indefinitely postponed.

The motion to indefinitely postpone was carried.

THE PRESIDENT.—I have asked the personal favor that, in what I believe to be for the best interests of the Academy, the Academy should adjourn to meet on the first Thursday in October. That request, by a vote of the Academy, had been denied. I now file my resignation.

Drs. Roosa, Agnew, and W. F. Cushman also offered their resignations.

DR. PURPLE.—I rise to a point of order. The Academy cannot act upon any of these resignations until we know whether or not the gentlemen have paid their dues. [Storm of hisses.]

DR. BOSWORTH.—I renew the motion that the By-laws be suspended, and that when the Academy adjourns it adjourn to meet on the first Thursday in October.

A rising vote was taken, 54 voting in the affirmative, and 16 in the negative.

The Academy then adjourned amid confusion.

A CASE OF PROCTITIS RESULTING FROM ACUTE METRITIS.—Dr. E. T. Hubbard, of Madison, N. H., describes a case under the above head. Dr. H. considers the complication quite a rare one. A married lady, twenty-eight years of age, after a long railway journey, aborted at the second month, since which time she has suffered considerably from irregular menstruation, and at times flooding quite profusely. I was called to see her in about three months after she aborted. Found uterus enlarged, very tender, and exuding a thick grumous discharge. Put her on ergot with bromide potash. At my next visit, in two days from that time, I found temperature $103\frac{1}{2}^{\circ}$, circulation 130, with dry tongue and considerable abdominal tenderness with pain shooting down the thighs and across the lower and back part of the pelvis, she having passed considerable tough, stringy mucus from the rectum, attended with considerable tenesmus, there being also a complete retention of urine. I diagnosed it as proctitis as a complication of metritis. I think it quite a rare complication. We may have considerable irritation of rectum, but no true inflammatory action, as there evidently was in this case.

A NEW WORD—DYSCARDIA.—M. Lubanski suggests (*L'Union Médicale*) the term dyscardia to signify difficult action of the heart. The word, he thinks, would mean for the heart what dyspnoea means for the lungs.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DEBATE ON DIABETES AT THE PATHOLOGICAL SOCIETY—THE GROCERS' COMPANY AND THE ENDOWMENT OF RESEARCH—COMPARATIVE PATHOLOGY—THE VICTORIA UNIVERSITY—MEDICAL TITLES.

LONDON, April 7, 1883.

DIABETES has been selected this year as the subject of the annual debate at the Pathological Society. This was opened on Tuesday last by Dr. Wilks. After a few remarks, in the course of which Dr. Wilks said that he had not himself found any changes in the fourth ventricle in patients dying from diabetes, Dr. Ralfe rose and brought forward his views. He distinguished two forms of diabetic coma, to the rarer of which he considered the term acetonæmia should alone be applied. He thought this condition was paralleled by those of acute yellow atrophy and phosphorous poisoning. He doubted the existence of free acetone in the urine, but thought aceto-acetic acid was probably present. If so, this would explain the high acidity of the urine so often observed in diabetes, the lactescent condition of the blood, and the intense fatty degeneration so noticeable in cases of acute diabetic coma. No other speakers advanced any theories, but confined themselves to criticisms. Several microscopic specimens were exhibited. The debate will be resumed in May.

Great outcries have been from time to time raised against the city companies and their disposal of their funds. The Grocers' Company, though, has shown its liberality on several occasions. The new wing of the London Hospital was built by its contributions, and now it again comes forward with a generous proposal to spend some thousands of pounds in the endowment of research.

Dr. Garrod's "Lumleian Lectures on Uric Acid," now in course of delivery at the College of Physicians, are interesting as containing the results of researches carried on by him for years, into the chemistry of the excretions of various animals. Dr. Garrod is, however, not alone as an investigator in the field of comparative pathology. The senior surgeon to one of the London hospitals has a model farm a short run by rail from London, to which he is accustomed to repair in his leisure hours. He has stocked it by purchasing diseased stock from neighboring farmers, and occupies himself in watching the pathological phenomena thus presented to him.

The Victoria University, Manchester, has received a charter to grant degrees in medicine to persons of either sex. Those who object to a multiplicity of titles now remark that this makes a twentieth medical licensing authority.

American physicians find it difficult to understand how it is that so many medical men call themselves Mr. The fact is, only university graduates (*i.e.*, M.D. or M.B.) can call themselves Dr., and in England the majority of practitioners are not university graduates in medicine. Some even who have taken a degree in arts do not take a degree in medicine. The older English universities require residence, and this arrangement practically excludes students at the London hospitals. This anomaly is not seen in Scotland, where the universities draw large classes. Consulting surgeons call themselves Mr., even though they are graduates. Physicians are nearly all graduates and style themselves Dr. In England most of the general practitioners are not graduates: those who are use the title of Dr. These anomalies are the growth of years, and are almost universally adhered to. Specialists are mostly surgeons, and use the title Mr. on their door-plates, though many who have degrees use them even when practising a surgical specialty. In

Edinburgh, every medical man is called "Dr." by the public, no matter what his qualifications. In Dublin, consulting surgeons often distinguish their mode of practice by prefixing "Surgeon" to their names.

DO THE LAWS OF A STATE DEFINE THE DUTIES OF INDIVIDUALS OR SOCIETIES IN MATTERS OF ETHICS?

SIR: A noticeable feature of Dr. Agnew's article on the Code question in a recent issue (*vide* p. 349) is that it does not in any way discuss the claims to recognition of the class or classes of practitioners who are welcomed by the new Code; but, aside from some rhetorical reference to liberty, progress, inalienable rights, etc., his remarks are devoted entirely to the legal aspect of the question, and the obligation which he claims is placed upon the medical societies of the State by the various medical acts of the State Legislature.

I shall not discuss at present the ethical principle involved by our recognizing in the new Code officially, as it were, the right of those whom we have formerly entitled irregular practitioners to exercise the duties of physicians; I will only call attention to our relation to the law.

Is there any one who will claim for a moment that the law created the Medical Society of the State of New York, or for that matter any other medical society. It is simply an impossibility for the law to exercise such a function. The first condition for the organization of a society of the nature of medical societies is the coming together or agreement of a certain number of individuals having certain interests and objects in common. Here we have the essential idea of the society upon which the law may confer certain corporate rights, which no doubt may, and in fact often do, amount to privileges. It is not necessary that there should be formal meetings and organization before the incorporating act of the Legislature, but it is necessary that there be men ready for the corporate work, and practically we find that these men are the originators and promoters of the special law. The laws of the State of New York have never defined the duties of individuals or societies in matters of ethics, while, on the other hand, in medical affairs these matters have been distinctly and properly left to physicians themselves, by the acts incorporating the various societies representing what we will call differences in opinions and practice.

The Act of 1880 can in no way be construed as compulsory in matters of practice, either as to the persons we shall accept as patients or the physicians whom we shall meet in consultation. These are matters of individual liberty, and any restraint put upon us concerning them by the law would be contrary alike to the spirit of the age and the genius of our political institutions. We are at liberty to respond to a call or to decline going. We can meet another physician in consultation or refrain from doing so, and the law cannot interfere; we are private citizens and not officers of the State, and I believe the best interests of society will be served by our continuing to occupy that relation to the law.

As members of the State and County societies we are at liberty to frame for our guidance such rules and regulations as seem best, simply keeping ourselves in this instance, as in other relations of life and in common with other citizens, free from violation of the laws.

If the regulations adopted seem onerous or unjust to individual members, they have the right of protest and of effort to secure action favorable to their views; and finally if the difference be irreconcilable, there remains the "inalienable right" of withdrawal.

The statement that the objectionable feature of the new Code in the matter of consultations with "legally qualified practitioners of medicine is permissive and not mandatory" seems to concede the question of law, but

certainly is no argument as to the question of right. This *permission* might serve as an incentive to objectionable affiliations, and the instances, now too common, of men serving low and selfish purposes with the indorsement of honorable associations and the livery of honest intent would be multiplied.

* I cannot see any additional light as to the legal status of the question in the opinions quoted from lawyers. It is possible that the "Professor of Municipal Law" may have been studying closely the various acts and projected acts of the Legislature concerning the city of New York during the last quarter of a century, and thus have become confused when he takes up the question of our rights and duties.

I trust our societies will continue free from any interference on the part of the Legislature comparable to that visited upon some of our municipalities, but, failing to maintain that freedom, it would be the part of wisdom to forfeit our corporate privileges and become simply voluntary associations.

Unless it can be shown that the law is compulsory in this matter, it is idle to raise the question for argument. I listened attentively to the discussion at the recent meeting of the State Society, and I heard no reason advanced in favor of the new Code, except that an adherence to the former Code placed us in hostility to the laws of the State, and a certain amount of sentiment as to a generous spirit, a progressive age, efforts for a higher standard of qualification and the like. These statements are not arguments, and become nonsense unless supported by a plain and distinct array of facts showing their truth.

I heard no one deny the legal right to decline a consultation with any physician, regular or irregular, so that the consultant felt that he preferred to decline, and I have yet to hear the proof from the champions of the new Code that a physician can be what we have termed an irregular practitioner and at the same time a proper and desirable person for fellowship in our societies or to be met in formal consultations.

In the discussion of the question that will occur till the meeting of the State Society in February, 1884, and at that meeting as well, it is desirable that we confine ourselves as closely as possible to the real merits of the case, and leave the idea of "courtesy to the Legislature," etc., alone; and, above all, unless some statutory obligation can be shown which will make us liable to some penalty for a particular action in the premises, let us hear no more of the law.

E. D. FERGUSON, M.D.

TROY, N. Y.

Army News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 14, 1883, to April 21, 1883.

WOLVERTON, WM. D., Major and Surgeon. Granted leave of absence for four months on surgeon's certificate of disability. S. O. 85, par. 7, A. G. O., April 13, 1883.

SHUFELDT, ROBERT W., Captain and Assistant Surgeon. To report in person to the President of the Army Medical Examining Board in session in New York City, for examination for promotion, on completion of which will return to proper station. S. O. 87, par. 10, A. G. O., April 16, 1883.

SWEETS FROM COAL-TAR.—A new substance, remarkable for its intense sweetness, being much sweeter than cane-sugar, has lately been found by Dr. Fohlberg, in the course of some investigations on coal-tar derivatives (*Journal of the Franklin Institute*). He designates it benzoic sulphonide, or anhydro-sulphamine benzoic abid.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 24, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
April 17, 1883.....	1	3	137	4	199	50	2	0
April 24, 1883.....	17	6	141	5	166	51	2	0
<i>Deaths.</i>								
April 17, 1883.....	1	6	21	3	27	20	0	0
April 24, 1883.....	0	2	20	3	26	26	1	0

Typhus fever has appeared among the children at St. Stephen's Home; the cases so far are very mild.

Deaths during the week ending April 21 were 676, of which 98 were from pneumonia.

A THERMOMETER HOLDER.—Dr. J. P. Savage, of Sioux City, Iowa, writes that an efficient thermometer holder is already in the market and has been for some time. He says: "Several years ago, when attending Bellevue, after breaking three thermometers in one day, by falling out of pocket while stooping to examine patients, I found a holder, made and now for sale by Caswell & Hazard, of this description: made of German silver, screw top, in top is a small staple to which is attached a chain; to other end of chain is attached a small 'safety pin.' The pin can be fastened in pocket out of sight. Since using this I have not lost a thermometer."

PRESCRIBING BY TELEGRAPH.—The *Electrician* publishes the following: "An employé of the Eastern Extension Telegraph Company, stationed at Cape Bolimao, Manila, had a narrow escape the other day, having taken ten grains of sugar of lead in mistake for a similar quantity of ammonia. He telegraphed for advice to the Hong Kong telegraph office. Dr. Hartigan, of that city, came down to the office and sent him advice per cable which resulted in his recovery. The distance between Hong Kong and Cape Bolimao is about five hundred and fifty-five miles. Probably this is the first time that a doctor has prescribed for a patient over five hundred miles away from him."

TO PREVENT PITTING IN SMALL-POX.—Dr. Emil Steiger, of Prairie du Chien, Wis., writes: "I have perused with much satisfaction the article of Dr. J. N. McChesney, on variola, but I was surprised not to see among the remedies against pitting a simple preparation which, in three epidemics during the last twelve years, has proved to me invariably successful. The fact that the preparation has given the utmost satisfaction in all cases where it was properly employed, including even those where I only obtained charge in the vesicular stage, may justify my presumption in publishing my treatment. Take of white lead (plumbum carbonicum), quantum lib., mix with linseed-oil q. s. to make a cream-like paste, add to the bulk about five to six per cent. carbolic acid, and apply with a large camel's-hair brush repeatedly, so as to keep the surface of the face, hands, etc., permanently and fully covered."

THE ASSOCIATION FOR PREVENTING THE RE-ENACTMENT IN THE STATE OF NEW YORK OF THE PRESENT CODE OF ETHICS OF THE AMERICAN MEDICAL ASSOCIATION has issued the following address to the medical profession of the State of New York:—

When very many members of a learned and liberal profession come to the conclusion that the rules by which their relations to their colleagues and to the public have hitherto been regulated have been injurious to themselves

and to the community, it is evidently the duty of persons having these convictions to labor for the abolition of such rules, and to state clearly the reasons why they should no longer be enforced.

The Code of Ethics of the American Medical Association which is now in force is identical with that which was in authority in the Medical Society of the State of New York, and which was abolished at the annual meeting of that society in February, 1882. It appears from the proceedings which led to the abolition of the Code in the State of New York that there had been a gradually increasing conviction among its members that some of the provisions of the Code were arbitrary and illiberal, and that a larger liberty should be granted the members of the society in the performance of their professional duties. After a full discussion of the subject, a vote of the society was taken, and by a constitutional two-thirds majority the old Code was abolished and a new one was enacted in its place. Among those who voted for the substitution of the new Code for the old one were many who preferred the entire abolition of the special ethical Code as unnecessary for the guidance of an honorable and learned profession. But the members who took this view of the subject were willing to unite with those who were less radical than themselves, in order to secure the abandonment or the most obnoxious features of the old Code.

At the annual meeting of the society in February, 1883, a strong effort was made by the advocates of the old Code to undo the work of the previous year and to re-establish in this State the Code of the American Medical Association. For this purpose no exertions were spared to secure the election of delegates who were in favor of the proposed retrograde movement. But the efforts which were then made failed to secure the votes of even a majority of the members of the society.

It is well known also that a strong effort is now being made, even by coercive measures, to secure in advance such a representation at the meeting of the society in 1884 as will undo the work which was done in 1882 and 1883. Believing that such action would be injurious to the honor, dignity, and usefulness of the profession, and to the best interests of the community, we earnestly entreat the members of the profession to give the subject their serious consideration, and to use all honorable and legitimate means to prevent the re-enactment of the present Code of the American Medical Association by the Medical Society of the State of New York. It appears to us to be particularly important to preserve to each member of the profession perfect liberty to decide for himself with whom he shall consult in order to secure the best interests of the sick.

The arbitrary rules which have to so large an extent controlled the actions of medical men, and which were originally designed to defeat the efforts of irregular practitioners to gain influence with the community, have signally failed to accomplish the object in view. These rules also have not commanded the respect of intelligent men in other professions. They have been regarded as belonging to the same category as the rules by which the various trades unions have infringed upon the individual liberty of their members, subjecting those who resisted the arbitrary action of the majority to the greatest indignities, pecuniary losses, and even personal sufferings. We call upon all fair-minded medical men to unite with us in freeing the profession from this stigma, and in giving all its members perfect liberty to practise their art in accordance with the dictates of their own consciences and with the enlightened opinion of intelligent men who are engaged in other pursuits.

There are indications that the movement which has begun in this State is destined to extend throughout the Union and to end in establishing a larger liberty than we have hitherto enjoyed, and in increasing the usefulness of our profession, and in giving it a more honorable position in the State and in the nation.

SCARLATINAL NEPHRITIS AND ITS COMPLICATIONS.

By JOHN H. RIPLEY, M.D.,

PROFESSOR OF DISEASES OF CHILDREN IN THE NEW YORK POLYCLINIC.

(Continued from p. 452.)

THE *prognosis* in scarlatinal nephritis is generally favorable. A very large number of those attacked completely recover. In addition to the symptoms already given (anuria and multiform casts) as rendering the prognosis unfavorable may be mentioned: 1, a severe form of fever preceding the nephritis, especially if complicated with true diphtheria; 2, a complicating pleurisy or pneumonia; 3, a late or an excessive dropsy, especially of the lungs, pleural cavities, or pericardium. In some cases, even where the nephritis seems not in itself severe, the child has become so enfeebled from the effects of the fever that it offers only slight resistance to this new malady and slowly dies of exhaustion. Pleurisy, so common in infancy and early childhood as a primary disease, is a frequent complication of scarlatinal nephritis. The pleura is probably the most commonly inflamed of all the serous membranes in this disease, and for obvious reasons the inflammation is more likely to be purulent than when occurring primarily in a previously healthy child. It is, therefore, a very serious complication and adds decided gravity to the prognosis. Pneumonia is less common than pleurisy and less dangerous, unless complicated with pulmonary œdema. Judging from my own experience, limited to two cases, both of which recovered, I should say that acute pericarditis is not as formidable a complication as one would suppose, theoretically. Extensive pulmonary œdema and large effusions into the pleural cavities only occur, as a rule, in consequence of a very feeble state of the vital powers, especially cardiac weakness, and hence are unfavorable lesions. The last two conditions are not infrequently mistaken for pneumonia. In a certain proportion of cases of pulmonary œdema, in which the air-cells over large areas are completely filled with fluid, the physical signs are precisely those of the second stage of pneumonia; and when only one lung is involved to this extent, the differential diagnosis must be made more particularly from a comparison of the vital signs with those of pneumonia. A change in the decubitus of a child for a few hours, when practicable, will determine the fluid to another part and so clear up the diagnosis. Dangerous *œdema glottidis* is a complication of acute Bright's disease, which I do not remember to have ever seen in a child.

Treatment.—The tendency of scarlatinal nephritis is, in a majority of cases, to terminate by self-limitation in recovery. The same general principles of treatment apply to all grades of the disease, but certain individual symptoms and the different complications should be met as they arise. A child suffering from a mild attack of this form of nephritis should be put to bed as soon as the disease is recognized, and an equable, moist, and rather high temperature (70° to 75°) should be maintained in the sick room. Although it is now generally conceded that the nephritis of scarlet fever does not, as a rule, arise from the patient's taking cold, still exposure to cold is a recognized cause of a similar form of nephritis, occurring as a primary lesion, and it is also known to cause exacerbations

of the disease in all its forms and stages. It is not improbable, therefore, that it may aggravate existing inflammation, or even determine it from a simple congestion in a small percentage of cases. The bowels should be kept rather free by means of some mild laxative, such as a combination of magnesia, senna, and rhubarb, but hydragogue cathartics are not indicated, although some physicians seem to hold the opinion that the appearance of albumen in the urine is the signal for drastic purgations. A simple nutritious diet, such as could be formed by alternating with milk, buttermilk, milk porridge, beef-tea, broths, and stewed tripe should be adopted. A diaphoretic mixture, as the *liquor ammonia acetatis*, completes all that it is necessary to do in mild cases. In the management of grave cases we have to deal with one or more of the following symptoms: 1, Partial or complete suppression of urine; 2, dropsy; 3, uræmia; 4, complications with other diseases.

1. *Partial or complete suppression of urine.*—In those forms of chronic Bright's disease in which we have a feeble heart and anæmic kidneys, much good may be done by stimulating the heart and irritating the kidneys with diuretics, thereby bringing about an increased flow of urine by an increased blood-pressure. But in the earliest stage of this disease the secreting portion of the kidney is already surcharged with blood, even to rupture of its capillaries, while later the terminal capillaries are so compressed by interstitial cell-infiltration and intratubular epithelial swelling, as to render the action of diuretics worse than useless. Says Klein: "Portions of the cortex are converted into pale, firm, round-celled tissue, in which the original urinary tubes of the cortex become gradually quashed and lost." These elements cannot be "washed out," and this is probably the only instance in which intelligent practitioners can be found treating an acutely inflamed organ by trying to drive more blood into it. Here it is done in violation of the ordinary rules of treatment, with the vain expectation of squeezing out a little more urine, and washing out intratubular *débris*. In my observation the opposite result has generally been produced. It is only when the disease is subsiding, either temporarily or permanently, as can be affirmed from concomitant symptoms, that the apparent diuretic effect of these active drugs is observed.

In the examination of a large number of sections of kidneys which had been taken from the dead body of a girl four years old, who had died of diphtheritic nephritis lasting only four days, the disease being accompanied with almost total suppression of urine, I observed the following microscopical changes: The Malpighian tufts were pretty uniformly congested and swollen, so much so as to distend their capsules. I saw no tufts showing compression from intracapsular exudation, and very few instances of capillary hemorrhage. The epithelium lining the tubes of the cortex was much swollen, coarsely granular, and the calibre of the tubes consequently greatly diminished. In some instances neither the nucleus nor the inter-epithelial markings could be made out, and in longitudinal sections such tubes appeared to be lined by one continuous granular strip. Quite a number of stumps of hyaline casts were seen in transverse sections, occupying mostly the narrow tubules, but some were seen in the convoluted tubes. The intertubular vessels were more or less engorged throughout all parts of the kidney, but there was almost entire absence of cell-infiltration as also of detached

epithelium in the tubes. Bartels objects to the theory that suppression is due to swelling of the epithelium and obstruction of the tubules by fibrinous casts, because "diminution or arrest of secretion is observed in the very earliest stage of the renal affection." In two of the worst cases which I have had under my care, mucus first appeared in the urine and then slight traces of albumen, forty-eight hours before the fulminant onset of the disease; the children meantime exhibiting no premonitory constitutional symptoms of illness. Considering, then, the pathological conditions which exist in bad cases of scarlatinal nephritis, the rational plan of treatment would seem to be to endeavor to re-establish the kidney circulation by reducing the congestion of the proximate portions of these vessels and thus favor absorption of the exuded material by both lymphatics and capillaries. "Among the curative measures," says Bartels, "a sustained diaphoresis deserves, unquestionably, the first place, not only in the symptomatic treatment of the dropsy, but as a measure which favors and promotes the retrogression of the inflammatory process in the kidneys." Theory and clinical experience alike sustain the correctness of this opinion. It will be observed that in the case which forms the text of this article, there was profuse and pretty constant voluntary sweating during the whole period of the inactivity of the kidneys, and to this vicarious work of the skin, mainly, I attribute the comparative mildness of the constitutional symptoms.

I have observed this fact before both in the nephritis of pregnancy and in that due to scarlet fever. One very remarkable case of the latter I saw with Dr. W. A. Hawes. The patient, a girl about five years old, although passing only a few drachms of urine at long intervals for several days, had profuse sweats, suffered principally from an irritable stomach, and ultimately recovered. Now, whether we hold that the skin can or cannot eliminate *urea* in any considerable quantity, the clinical fact remains that free perspiration will generally relieve a patient, temporarily at least, from what we call uræmic poisoning. But, according to Foster,¹ "the toxic consequences are due not to the presence in the system of the large quantity of urea, but of other, at present undefined, substances, which have at the same time ceased to be excreted," and these, perhaps, may be more freely excreted by the skin. Of the different methods of inducing perspiration in cases in which it does not occur spontaneously, one of the best is the moist, warm pack. This has the advantages of simplicity, practicability, and efficiency. The following is the plan of preparing it: A bed covered by woollen blankets should be made ready. Then a sheet or sheets several folds thick, loosely wrung out of warm water should be closely wrapped around the child so as to completely envelop it, except the head, and the child thus enveloped be tucked in between the woollen blankets and allowed to remain for at least two hours, unless the coverings become sooner cold, when the pack can be renewed. In a bad case it may be necessary to repeat the pack several times during the twenty-four hours and perhaps every day for several days. Great care should be taken in the intervals to avoid exposing the patient to the cold air. In case the child prove refractory, the hands and arms may be pinioned and the coverings fastened securely by safety-pins or by means of tapes, or a simple and often better way is to keep the patient partially under the influence of morphine while in pack. When taken out of the pack the body should be thoroughly rubbed with a rough towel until the surface is dry. The warm bath, even when facilities for its use are ample, can only be recommended to a limited extent. Many children are terribly afraid of it. In some it produces speedy and alarming syncope. In general, it has a tendency to exhaust the patient if prolonged or frequently repeated. The hot air bath is very highly prized by G. Harley and others, as not only greatly increasing the cutaneous but

also the pulmonary elimination of the urinary poisons. It may serve as a good substitute for the pack with older children in a small proportion of cases, but it will generally be found less practicable. *Dry cupping over the kidneys* appears occasionally to do good. Any one who has seen much of cupping for œdema or active congestion of the lungs must have observed how speedily efficacious it often is in those conditions. I believe, with Tyson,¹ that the cups should be removed before stagnation and rupture of the capillaries occur. From five to ten minutes is sufficiently long to allow them to remain on. In delicate, nervous children it is better to give chloroform while applying them. Large, hot poultices of flaxseed meal placed over the same parts, either instead of the cups or following them, have, I think, a deserved reputation. Whether the admixture of foxglove leaves and the meal is any more efficacious than the latter alone, I cannot say, but I frequently use it. Of the internal remedies, jaborandi or its alkaloid, pilocarpine, morphine, veratrum viride, and aconite are, perhaps, the most valuable. After other means of inducing perspiration have succeeded, a dose of from five to twenty drops of jaborandi repeated every two hours, according to the age of the child, has a tendency to keep up a gentle moisture of the skin, and is often a more satisfactory way of giving the drug than to give larger doses at longer intervals. When the disease is accompanied with a high temperature and a rapid, strong pulse, small doses of the tincture of veratrum viride, given every two hours, have a very marked beneficial effect on both temperature and pulse, and secondarily on the action of the kidneys. My friend, Dr. L. D. Sproat, who prizes it highly in puerperal peritonitis, thinks that the system will tolerate much larger doses if it be combined with syrup of ginger. He certainly succeeds in giving it with a free hand. Tincture of aconite is less certain to produce its specific effects than veratrum, but it is not so likely to induce vomiting and is less dangerous when its use is prolonged. In regard to its vaunted cures of the angina of scarlet fever, or that of any other disease. I can only say that in my hands it has been a complete failure. Morphine may be used to control restlessness, and also, in conjunction with other means, to produce diaphoresis.

2. *Dropsy*.—In all cases in which the effusion is moderate, whether it be limited to the superficial cellular tissue, or invade also one or more of the large serous cavities, the treatment is substantially that recommended above. Should great œdema of the lower extremities exist, together with general anasarca, giving rise to distressing symptoms, and resist the faithful efforts to remove it by diaphoretics and catharsis, a few small punctures made with a sharp bistoury into the cellular tissue of the lower part of the legs will sometimes accomplish, by mechanical drainage, what we have failed to do with other means. Such punctures generally remain open for several days, and often excrete a surprising amount of the dropsical fluid. I do not remember having seen erysipelas or sloughing follow as a consequence of these punctures (a danger feared by some), although I have resorted to it many times, mostly, however, in chronic cases. Indeed, I believe the instances are rare in which this procedure will be found necessary in acute cases. An extensive anasarca will generally be borne with comparatively little discomfort if the thoracic organs are not involved, and it will ultimately yield as the kidneys recover. But so long as the dropsy exists to any great degree, it not only endangers the life of the patient from exhaustion, but also especially as a bad complication in case of any acute serous inflammation. (Edema of the lungs is best treated, locally, by repeated dry cuppings and by large hot poultices covering the entire thorax. Should hydrothorax or hydropericardium seriously threaten life, aspiration may be resorted to. Aspiration in hydrothorax seems not to be attended with

¹ A Text-Book on Physiology, p. 448. New York, 1880.

¹ Op. cit.

the same degree of danger from purulent change in the fluid, as in pleurisy with effusion of serum. The fluid usually remains unchanged after repeated tapplings. If *adema glottidis* occur and give rise to dangerous obstruction, tracheotomy should be performed without delay. I believe it is a very rare complication of this disease.

3. *Uræmia*.—The most common manifestations of uræmic poisoning in children are, great gastric irritation, painful and exhausting diarrhœa or dysentery, extreme restlessness. Convulsions rarely occur.

The treatment of these symptoms has necessarily been somewhat considered in the general management of the nephritis; for, of course, the same general principles apply throughout the course of the disease, whatever special symptoms may arise. The indications are, first, to eliminate from the system, so far as we are able, the poisons which are the cause of the symptoms and which the kidneys are powerless to remove, and, second, to enable the patient to tolerate, until the kidneys assume their functions, such portions of those poisonous matters as remain in the system in spite of our efforts to expel them. The proper course to pursue in order to fulfil the first indication has already been considered. There is one danger, however, to be borne in mind, both in the treatment of dropsy and uræmia, and that is the danger arising from hyperpurgation. I verily believe that quite a number of children are sacrificed in every epidemic of scarlet fever by the too heroic administration of cathartics—especially the preparations of mercury. Under the excessive use of cathartics, the irritability of the stomach is increased, nutrition is impaired, and the patient's strength fails, while transudation through the weak and thinned walls of the capillaries more than keeps pace with the fluid removed by the bowels. It is unwise, in my opinion, to carry cathartics beyond the inducing of two or three liquid passages a day.

To control gastric irritation a careful management of the diet is of primary importance. Whatever article of food or drink be given should be taken only in small quantities. A teaspoonful given every fifteen minutes or less will be retained when a tablespoonful every hour will be vomited. Koumyss, buttermilk, sweet milk with lime-water, clam broth, milk porridge, and grated smoked beef are among the nutrients most likely to be retained. If prostration be a prominent symptom, plain brandy with iced water or champagne may be indicated. From five to twenty drops of the U. S. solution of morphine given hypodermically, or by the stomach, and repeated every three or four hours, if need be, is almost a specific. Hydrate of chloral in from five- to fifteen-grain doses by the rectum in a small quantity—half an ounce to an ounce—of water sometimes acts most satisfactorily. A mixture of a few drops of chloroform with paregoric and syrup of acacia occasionally does well.

For the diarrhœa it is generally well to begin treatment by giving a small purgative dose of calomel and compound jalap powder, and then to hold it in check with a mixture of opium, tannic acid, and cinnamon water. It is not desirable, of course, to produce constipation, but only to modify the action of the bowels.

A very effective way of managing the dysentery is, first to give a large enema of hot water, so as thoroughly to wash out the rectum and relieve the congestion of the gut, in a measure, at least, and then to follow this by an enema of half an ounce of warm water containing a few drops of laudanum, according to the age of the child. These laudanum enemata may be repeated after each passage; the hot-water injections twice or three times a day. If the rectum will not retain the medicinal enemata, then opium in some form, either alone or combined with very small quantities of calomel, can be substituted. The *acetum opii* of the U. S. P. is an excellent preparation, and not likely to be vomited. No doubt these intestinal troubles depend on various pathological conditions, but they have a common etiology, and the most valuable remedy in all cases is opium. Extreme

restlessness in a certain proportion of cases is a painful and exhausting symptom. It usually yields promptly to hydrate of chloral, especially when this drug is combined with small doses of morphine. I believe that proportionably much larger doses of this drug may be given with safety to children than to adults. Chloroform and morphine increase its effect, a fact to be remembered when prescribing maximum doses.

Convulsions.—Although convulsions are so common in infancy and early childhood from the outset of other, often comparatively slight diseases, uræmic poisoning, even when profoundly affecting the nervous system, rarely produces convulsions. I have seen two instances of probable uræmic convulsions in new-born children, where the mothers suffered from uræmia both before and during labor. One reason why convulsions do not often occur in this condition is, probably, that the accumulation of the poison in the system takes place slowly, and, as may be shown in several other instances of diseases affecting the nerve-centres, the tolerance is much greater when the invasion is gradual. If this complication arise, and the convulsions recur in spite of efforts to eliminate the poison which causes them from the system, I am satisfied from my experience with uræmic convulsions in adults, that morphine given hypodermically is the most effective remedy that can be used. When, in 1870, at the New York County Medical Society, Dr. F. D. Lente advocated the hypodermic injection of morphine in puerperal convulsions, which, as he said, he believed nearly always depended on uræmia, his remarks met with a cold reception. Since that time, more especially since the publication of a paper on the subject by Prof. Alfred L. Loomis,¹ the remedy has been steadily growing in favor. Now it is rare to find an intelligent practitioner of medicine who does not advocate its use in obstinate cases.

The most common complications consequential to the nephritis are pleurisy, pneumonia, endocarditis, and cellulitis of the neck; less common are pericarditis and erysipelas. Pleurisy, the most frequent of all the complications, should be treated constitutionally in the first stage with morphine, in sufficient doses to relieve the acute pain, and, locally, by large hot poultices. If there be no general anasarca, a small blister may be applied over the seat of the pain before poulticing. If serous effusion follow in the second stage and cause severe dyspnoea, aspiration should be resorted to, but, unless the quantity of fluid be large, it is better to treat the case expectantly, for, as the kidneys resume their functions, the fluid generally begins to diminish.

In case the exudation be purulent at the outset, which it is very likely to be, or become purulent later, surgical interference should be delayed until the active stage of the nephritis subsides, unless embarrassment to circulation and respiration be great or septic fever threaten the child's life. If either of these emergencies arise, recourse should be had to aspiration. In a small proportion of cases, when fluid is removed in this way, the pleural cavity will not refill; but generally the relief is only temporary, and subsequent radical treatment by free incision into the pleural cavity and the insertion of a drainage-tube becomes necessary. In uncomplicated empyæmas I prefer to open the chest at once, and, in my experience thus far in children, the cases have uniformly terminated in recovery. I have never found it necessary to remove a portion of rib in any of these cases, and I believe it to be an entirely unnecessary and unjustifiable operation. I doubt whether any advocate of the practice would be willing to have a child of his own deformed by this procedure.

Pneumonia should be treated substantially as under other circumstances, namely, locally by hot poultices enveloping the entire thorax, and by the internal administration of diaphoretics, sedatives, and stimulants

¹ MEDICAL RECORD, vol. viii., p. 361.

when required. *Endocarditis* generally gives rise to little pain or constitutional disturbance, and its existence is frequently first suggested by physical examination. If the action of the heart become irregular or tumultuous, convallaria or digitalis and opium will be indicated early in the disease, and carbonate of ammonia in small doses if there be reason to believe obstructive exudation is taking place. *Cellulitis of the neck*, which began during the progress of the fever, not infrequently lights up afresh when the nephritis sets in, and goes on to suppuration. The most important point in the treatment of it is to make a free incision into the inflamed mass as soon as pus can be recognized, in order to prevent the burrowing of matter and extensive destruction of the soft parts. I have known of one instance of death from hemorrhage due to sloughing of the external jugular vein. *Erysipelas* should be treated on general principles, except that, perhaps, frequent doses of the muriate tincture of iron are especially indicated. *Pericarditis* is probably more frequently caused by scarlatinal rheumatism than by scarlatinal nephritis, but it occasionally occurs from the latter disease. It is sometimes secondary to a pleurisy, especially of the left side. Prof. J. Lewis Smith says,¹ speaking of the complications of scarlet fever: "Serous inflammation, especially that affecting the peritoneum, pleura, or pericardium, is a common complication independently of the rheumatic affection. It occurs during the desquamative period, etc." Are not these inflammations thus referred to often caused by an acute nephritis?

Aside from the general treatment of the causal disease of pericarditis, other remedies will be indicated according to the symptoms present. When the area of inflammation is small and the symptoms mild, special drugs are not required. Cardiac weakness will call for digitalis and stimulants. Pain, dyspnoea, and restlessness will be relieved by morphine or chloral and the local application of hot poultices. If, at a later period, a large effusion takes place, and the danger to life be imminent, aspiration will be demanded. Sudden or violent exertion is liable to be followed by fatal syncope, and hence quietude in bed should be maintained throughout the entire course of the disease.

EARACHE IN CHILDREN.²

By SAMUEL SEXTON, M.D.,

NEW YORK.

It is probable that in no affection requiring prompt treatment for the relief of severe pains is there greater need of both scientific and practical knowledge of the subject than in children's earache. The urgency of the symptoms in these cases, however, would seem to often prevent so careful a study of their clinical history being made as their treatment requires, and they are, therefore, much too often regarded as exclusively local in their nature and treated accordingly. Were the excruciating pains in acute inflammation of the middle ear alone considered, local treatment would, indeed, seem to be imperatively demanded, almost to the exclusion of any attention to the remote causes usually present. But we should not be unmindful, however urgent the local symptoms may be, that when the causes of the disease have been ascertained we may then more surely, and very often even more expeditiously, relieve the patient by striking at the origin of the difficulty; thus a remedy applied to a carious tooth may cure an otalgia, a reversal of the practice of the ancients, who made application to the ear for the relief of toothache.

The occurrence of earache is well known to be most frequent at night, although it may announce itself during the waking hours, when it seems to be much better endured, probably owing to the fact that the nervous energies of the patient are then more active and the surroundings

more reassuring. It is usually during the night that the patient, on waking up from his first sleep, when less capable of enduring the pains of earache, gives way to his sufferings. It were better for him, too often, to have submitted in silence to his tortures than to have disturbed the sleeping household; for it will generally be found that with more energy than skill the patient's ear has been made the receptacle of a most indiscriminate variety of stimulant, anodyne, irritant or other substances; sometimes the visible parts will in this manner have been blistered, or even greater injury may have been done to the deeper structures. Again, in other cases, the do-

Fig. 1.

Fig. 2.

mestic economy is urged to its utmost capacity in poulticing, steaming, douching, fomenting or otherwise heating the ear. The methods pursued in these cases too often seem to depend on the number and individual views of the lay consultants present, and it is fortunate, if after any, or even all of these measures have been tried we do not find that the domestic treatment has converted what might have been a simple affair into a severe and probably protracted one.

Examination of the ear.—When the physician encounters a case of this kind it will often be found necessary to first bring order out of chaos before attempting to make an examination, but a little firmness on his part is usually quite sufficient to accomplish this, and to also tranquilize the patient. During the temporary lull which usually ensues, the patient may be held in the nurse's lap while the examiner promptly but gently proceeds to ascertain the extent and nature of any local lesions which may give rise to the earache.

Instruments employed in making examinations.—A head-mirror had best be employed, in order that both hands may be free for necessary manipulations. For the examination there will be required specula (I myself prefer those known as Gruber's), an effective metal or bulb ear-syringe, a vuleanite cotton-wool carrier, and a supply of absorbent cotton-wool. One should not omit to have a cup of quite warm water near by, that no time may be lost should any syringing be required. Hard rubber and

¹ Diseases of Children, fifth edition, page 195.

² Read before the Practitioners' Society of New York, April 6, 1883.

glass syringes should both be avoided in cleansing the ear; the former kind are very seldom found to work freely, owing to their imperfect construction. The calibre of these syringes is uneven and the vulcanized surface seems illy adapted to the purpose, on account of its offering too much friction to the packing. The glass syringe is of scarcely any service whatever.

Either of the syringes shown (Fig. 1, a brass syringe, and 2, a bulb syringe) in the cuts will be found to be free from the objections referred to above.

In these cases one must conduct the examination as expeditiously as possible, not forgetting that the parts to be examined are nearly always sensitive to the touch, and that the patient's fortitude is usually by no means great. If there be swelling and redness of the auricle or antiauricular parts, manipulations will be yet more painful.

Nature of discharges.—At first syringing had best be avoided, for fear of increasing the pains and discomfort; besides, any secretions lying in view should be inspected before removal, since the significance of their appearance is of value in diagnosis and treatment. Thus it is known that the cutaneous lining of the external auditory canal does not, under any circumstances, secrete mucus. Purulent secretion from the canal itself is comparatively infrequent, but a limited quantity is discharged from maturing furuncles, and can usually be seen escaping from the swollen wall of the canal. The serous constituents of the blood exude slightly in acute eczema and from wounds. But the diagnosis in all of these conditions is not difficult. There is one variety, however, of acute catarrhal inflammation of the middle ear which is liable not to be so readily recognized by the inexperienced observer in consequence of a coexistent exudative dermatitis confined to the inner end of the canal and the outer layer of the drum-head; the inflammation is generally superficial, the consecutive necrosis and exfoliation of the epidermis being associated with more or less whitish and somewhat inspissated exudative matter, which sometimes completely fills the inner end of the canal. In these cases the membrana tympani frequently escapes perforation.

In acute purulent inflammation of the middle ear the discharge is generally more free than in any of the conditions above alluded to; it is at first, in most cases, serous or sero-sanguinolent, but soon becomes mucopurulent. The mucous flocculi, observed more readily floating about in the water if syringing has been done, unerringly points to the existence of a perforation in the membrana tympani. Frequently the simple inspection of the ear, as described above, will suffice to establish a diagnosis upon which the treatment at this stage may be planned, since the clinical history as regards colds, etc., may afford sufficient data to remove all doubts, if any yet remain.

When it seems important to make a more complete examination of the ear, the canal may be gently syringed with quite warm water and afterward dried with cotton-wool wound about a proper carrier; or perhaps the latter appliance used as a mop may be quite sufficient for our purpose. If I may venture to recommend so unimportant an instrument as a cotton-wool carrier, I will here suggest the advantages of employing a polished vulcanite rod, properly shaped, for the uses to which a metal probe is sometimes put in cleansing the ear; it is light and will not injure the parts by its momentum when introduced into the organ. No care is too insignificant to occupy the surgeon's mind when manipulating the ear; the touch, the instruments, and every feature of the treatment should be of the gentlest kind; even the warming of the specula and other instruments employed, by holding them for a while in the closed hand or otherwise, should not be neglected.

When the canal has been freed of secretions, etc., its walls may then be viewed and in many cases the drum-head can also be seen; but when the latter is not visible, owing to accumulations and swelling of the canal's walls,

we may often observe a pulsating bubble in the discharge which wells up out of the middle ear. From this air-bubble there is a light reflex and the vibrations of the artery in the carotid canal impart the pulsations seen: this phenomenon indicates the membrane's perforation. Closure of the canal attended with pain may happen from several causes, as in consequence of circumscribed or diffuse inflammation, from dermatitis, or from the hard, dry scales which sometimes form subsequently from the exudative matter; from erysipelas or eczema; from collections of cerumen, and from the presence of foreign bodies.

Remote causes.—The above are conditions which are recognizable to the observer under proper illumination, but it very often happens that a patient will present himself where no such easily recognized cause will be found. On the contrary, the canal and drum-membrane will appear to be free of any disease while the child suffers intensely from earache. We have here to deal with a perplexing case of neuralgic otalgia, which may be due to dental irritation or to a draught of cold air falling upon the ear. I have seen cases of earache in midsummer induced by cold sea-air blowing into the ear, and the entrance of cold sea-water is also a well-known cause; these agencies are likewise sufficient to induce inflammation of the canal and middle ear.

In a very large number of the earaches of childhood the causes are to be sought elsewhere than in the hearing organ itself, and they will be found to depend, for the most part, on nervous sympathy; the most prominent are dentition, dental caries, and colds in the head. Thus nervous impulses propagated from regions remote from the ear may give rise to pains in the ear—neuralgic otalgia—without perceptible hyperemia, or the intensity of the congestion arising in a part so richly supplied with blood-vessels may manifest itself as an acute aural catarrh.

The effect on the ear of taking a severe cold in the head is by no means always dependent on an extension of the catarrhal inflammation from the upper pharynx along the Eustachian tubes, but it will be found that immediate aural inflammation may also be a consequence of the same influences that affect the pharynx; in fact, the throat, the Eustachian tubes, the middle ear, and the mastoid antrum and pneumatic cells of the mastoid may all be affected simultaneously from cold. During the prevalence of influenzas the ear is frequently thus affected.

Recurrent earache is an exacerbation during the course of chronic inflammatory processes in the middle ear, usually occurring as a consequence of taking cold; it is in such cases that the ear is said to "gather and break," or to "run off and on."

In the *exanthemata* earache manifests itself in a more virulent manner than usual, and while, owing to the particular dyscrasia present, the patient is more obnoxious to these attacks, the etiological conditions are similar.

The age at which earache occurs.—Earache may occur in children soon after their birth, from acute or chronic catarrh of the upper pharynx and middle ear. These processes are not usually painful, but may become so when the drum-head has been thickened. Painful aural catarrhs, however, are not common before the process of first dentition begins, and they are of exceptional occurrence after the second permanent molar tooth has been cut, which event usually happens about the twelfth year.

In some children earache is experienced from dental caries almost as soon as the first teeth are cut. My attention was drawn to the frequency of this condition many years ago, on examining the ears of the children of a public institution; and subsequently I made a more thorough study of the subject, during which the ears and teeth of some eighty children in the parochial school of the Church of the Assumption were examined. A large number of casts of the teeth of these children were taken, and scarcely any of them were found to be

free from dental irritation. An example is¹ exhibited in Fig. 3.

Oral irritation, it goes without saying, is extremely common throughout childhood, but sympathetic aural pains may not be experienced unless a cold in the head should supervene; the habit once established, however, the eruption of every tooth may become the signal for pains in the ear.

Catarrhal inflammation of the middle ear, which gives rise to most of the earaches experienced in childhood, may conveniently be divided into two forms: (1) The first is an affection of the mucous surface of the lining of the tympanum only, and is characterized by a greater or less flow of mucus or of serum into the tympanic cavity;

FIG. 3.—Casts of the teeth of a school-girl, twelve years of age; from the author's cabinet; the casts are represented as being held together by a hinge. 1, 1. The second bicuspid teeth of the upper jaw, both of which have been crowded out of place as they erupted by the remains of the fangs of the temporary second molar teeth; these fangs, which have been too long retained in the gums, are seen in the cut just inside the second bicuspid. The retention of the fangs, together with the crowded and irregular condition of the permanent teeth which have just been cut, gave rise to much irritation. This anomalous condition of the teeth is by no means an unusual occurrence where the teeth are neglected. 2, The left upper six-year molar tooth, which is very carious. 3, 3. The two lower six-year molars, both of which have been destroyed by caries. The little girl from whose teeth these casts were taken suffered from deafness and frequent attacks of pain in both ears, and, as she herself expressed it, "the decayed teeth had ached very much all around."

(2) the second form occurs along with or is consecutive to the first, and consists in an inflammation of the sub-mucous connective-tissue and of the periosteal layer of the membrane. The tympanal walls being everywhere invested by a membrane which possesses the double character of a mucous and periosteal membrane, the inflammatory process is attended by an abundant secretion and is characterized by its painfulness. The mucous layer, when swollen, very much reduces the size of the drum cavity, and thus also obstructs the entrance to the Eustachian tube through which the normal drainage of the parts takes place. In both stages, or varieties, of the disease spontaneous rupture of the membrana tympani may take place under the pressure of accumulated secretions sooner or later. The pains experienced are sometimes very slight when the membrane gives way early, but in some constitutions the disturbance is always attended with suffering. In a certain number of cases the attack now speedily subsides, and, if no injudicious interference prevents, recovery is rapid and complete. Where the onset, however, has been severe, and deeper tissues become more particularly involved, the pains are

more severe and continue longer, secretions in the meantime remaining free or ceasing altogether.

In earache the attack is frequently preceded by a rigor, and afterward alternations of chill and heat continue until the local disease is fully established. "The first thing a patient complains of, in the midst of these symptoms, are acute pains deep in the ear, which are described as pricking, burning, tearing, boring, and dragging. These pains are usually confined to one ear, and are aggravated by every motion of surrounding parts, as in chewing, sneezing, coughing, stooping, and the like."¹ In pure neuralgic otalgia there is not the same sensitiveness to motion, and in proportion to the predominance of this feature of earache will the patient manifest restlessness and a desire to toss about while in bed, or to walk or be carried in the nurse's arms.

The seat of pain in earache.—I have stated above that the tissues involved in inflammation of the middle ear consist of a membrane which performs the double duty of mucous membrane and periosteum. The sensitiveness of this structure is extremely great, for it is not only richly supplied with blood-vessels, but also wonderfully well provided with sensory nerves. These latter compose the tympanic plexus, a diagram of which is here shown.

FIG. 4.—Diagram of the tympanic plexus (Rüdinger). 1, Oculomotor nerve; 2, trigeminal nerve, with the gasserian ganglion; 3, first branch of the trigeminal nerve; 4, second branch; 5, entrance of the same into the sphenopalatine fossa; 6 and 7, superior maxillary nerve; 8, sphenotympanic nerve; 9, descending palatine nerve; 10, Vidian nerve; 11, large superior petrosal nerve; 12, buccinator nerve; 13 and 14, pterygoid nerve; 15, chorda tympani nerve; 16, carotid plexus of the sympathetic; 17, petrosal ganglion of the glossopharyngeal nerve; 18, 19, and 21, vagus, accessory nerve of Willis, and hypoglossus; 20, facial nerve; 22, nervi carotico-tympanici; 23, tympanic, or Jacobson's nerve; 24, small superficial petrosal nerve; 25, nerve of the tensor tympani; 26, tympanic plexus; 27, branch for the oval window; 28, branch for the round window; 29, large, deep-seated petrosal nerve; 30, branch for the Eustachian tube; 31, division of the Vidian nerve into its two branches; 32, anastomosis of fasciculus of the Vidian nerve.

This anastomosis derives supplies from sources most extensive; thus by means of branches from the otic ganglion the inferior maxillary nerve is brought into intimate relations with it, and the petrosal ganglion of the glossopharyngeal nerve supplies the tympanic branch, or Jacobson's nerve, which constitutes a large portion of this anastomosis. The carotid plexus of the sympathetic sends a branch to the glossopharyngeal and thus establishes a communication between the ear and the superior cervical ganglion of the sympathetic nerve. Through Meckel's ganglion, by means of the Vidian nerve the superior maxillary of the fifth pair of nerves also is connected with the tympanic system. Besides these there are other connections which may be seen by consulting the diagram. In describing these parts Burnett² calls attention to the importance of bearing "these relations in mind when considering certain neuralgias in and about the ear, which might otherwise be puzzling."

Diagnosis.—Sufficient significance has already been given to the local and remote causes of earache, or rather the conditions that give rise to this symptom, to indicate their relative importance. In neuralgic otalgia it will often be found that there is an entire absence of local

¹ From the author's "Causes of Deafness among School Children," etc., Circulars of Information of the Bureau of Education—No. 5, 1881. Government Printing Office, Washington, 1881.

³ Treatise on the Ear, p. 36. Philadelphia, 1877.

inflammation, and in this as well as in all painful affections where no sufficient local influences can be found, it is well to cast about and endeavor to discover any sources of reflex irritation, for treatment directed to the remote origin of the difficulty is in many instances the most effective and often of itself sufficient to cure the patient.

As regards the significance of pain in and about the ear, it is important to differentiate as between pain and tinnitus aurium in all cases. The noises in the head and the autophanous reverberations of the voice of the patient, symptoms alike confusing and distressing, are often even more unbearable than the pains; and when the two coexist, as they frequently do, they are indeed almost indescribably tormenting. Noises in the head may constitute the entire cause of distress in conditions where active treatment may not be required, and one should, therefore, keep this fact in mind when examining a case of children's earache, since the patient is frequently unable to distinguish between subjective and physical signs. In a long experience I have nearly always found it very difficult to obtain from patients a clear description of their sensations under these conditions. Not the least satisfactory have been the definitions sometimes obtained in the humbler walks of life, and the following terse and expressive phrases seem to most explicitly describe the feelings; thus a woman who once came to my clinic at the New York Eye and Ear Infirmary, in reply to my request to describe her symptoms, said that she had "roaring pains in the head," and on another occasion a patient, also a woman, described somewhat similar phenomena as being like a "noisy dizziness."

Respecting the sensations which are experienced in the ears during attacks of aural catarrh it may be said that, in addition to a greater or less degree of deafness, there is nearly always a feeling of the ears being "stuffed up," together with tinnitus like escaping steam, buzzing, ringing, and whistling sounds, etc.

Meningitis, which sometimes coexists in the more grave cases, either arising from the same common cause or consecutive to otitis media, is not always easily distinguishable from the latter affection, but fortunately in most cases the treatment is the same in either.

Duration.—Earache may continue several days in the acute state, always worse at night, before spontaneous rupture takes place, when there is immediate relief experienced in most cases. When a carious tooth is the cause of the trouble, its duration will be more indefinite. Under treatment, the attack may be cut short in many instances and nearly always may be ameliorated.

Treatment.—The desire to relieve pain in these cases generally leaves prospective measures to be last considered, and, indeed, the surgeon will usually find that local measures have been already carried to excess. It will by no means always be easy to proceed at once to make the necessary examination upon which a plan of rational treatment may be founded, where there are a number of anxious attendants who have already emptied into the sufferer's ear everything their resources could command before availing themselves of skilled counsel. It will usually be expected that the means at the command of the medical adviser will enable him to propitiate the disturbing spirit by the contribution of some new libation, unknown to common mortals; this requirement may be met where the condition of the canal admits of deep applications being made. A remedy that will in some instances be found serviceable for this purpose is belladonna; the deeper parts may be painted over with a small quantity of a mixture composed of equal parts of unguentum belladonnæ and vaseline, or four drops of a five-grain solution of the alkaloid sulphate of atropine may be instilled into the upturned ear by the surgeon himself, who can alone apply these remedies properly. They should be warmed before being used, and, it is needless to say, should not be wasted upon the outer portion of the canal. Of course it would be useless to make these applications

when the canal was not free of secretions. In a certain number of cases this medication will be found to be an efficient palliative, as in periostitis of the inner extremity of the canal, as shown by redness and swelling, and when the membrana tympana is inflamed; any considerable effect on the nerves more deeply situated in the tympanum is, however, not to be expected, unless, as might exceptionally happen, a few drops of the solution passed into the middle ear through a perforation in the drum-head.

Dry warmth, when grateful, may be applied, either as heated air conducted into the ear, or by means of heated pillows, etc. In some instances gentle fomentations or steaming may be employed, but active syringing, douching, steaming, poulticing, or even mopping out the canal, are all of them to be specially avoided, as they usually do more harm than good, and in very many instances are positively injurious.

Myringotomy.—Sometimes there is no discharge from the inflamed parts, and then the question of puncturing the drum-head arises. In regard to the necessity of this operation there has been much discussion among otologists, some authorities favoring its performance in nearly all cases, especially when the membrana tympani is much inflamed or is perceptibly protruded by the pressure of secretions. It is a matter, I believe, where a great deal of judgment is often required to be exercised, more, in fact, than is generally thought necessary. In my own experience I have found that a bulging or much-inflamed drum-head by no means always demands this procedure for the relief of the patient, for I have often found that under other treatment the pains and other inflammatory symptoms will speedily subside; secretions will be reabsorbed or partly escape through the Eustachian tube, the membrane will rapidly clear up, and all the parts assume a healthy appearance.

But occasionally the membrana tympani will be found to have been much toughened by previous acute or chronic inflammation, or the existing attack may have occasioned thickening of its inner mucous or outer cutaneous coat. If now it is found that there is undue and painful pressure of secretions whose escape is prevented by closure of the Eustachian tube, we shall be warranted in liberating them by means of myringotomy. But this operation is not always unattended by considerable pain, and, moreover, if well performed, not to be done without skill, and we should not, I am convinced, resort to it as a mere antiphlogistic measure, with the belief that, even if useless, it is at all events harmless. When the parts to be operated on are not well seen, the procedure is at best an unskilful stab, the consequences of which are not always favorable. When myringotomy is necessary, however, it should be promptly done, and usually while the patient is under the influence of an anæsthetic.

The employment of leeches in my own experience has not been satisfactory, and I have for a long time past ceased to use them. I am aware that custom still demands the use of these sanguinary worms in certain quarters, but I doubt not their usefulness has been much overestimated.

The remote abstraction of blood from the cheek in front of the tragus or, even from the concha, will not permanently relieve congestion of the deeper parts; and, moreover, it is not the stagnant blood that is withdrawn, but the more freely circulating fluid. In a certain number of cases, the bite of the leech seems to give rise to irritation, and what wonder that it does when we consider that its mouth, according to Baird, is provided with three jaws, and "each of these is armed on its edge with two rows of very fine teeth, which penetrate the skin by a motion resembling that of a semicircular saw." Besides the irritation from the bite, their appearance is calculated to frighten the child, and oftentimes the bleeding is arrested with difficulty.

Among the more valuable drugs which are serviceable in earache from any cause in which nervous excitability

is a feature, I know of none equal to aconite, gelsemium, or pulsatilla, five or ten drops being added to half a glassful of water, and given in teaspoonful doses as required.

In my own experience the relative efficacy of these remedies has been found to be about in the order mentioned above. In very young children, I give the preference to the pulsatilla. It is important in employing these drugs to secure a tincture made from the fresh plant.

The sulphurated lime, which I have long employed in affections of the ear, I still regard as of the greatest service. I have scarcely ever seen a case where this medicine produced nausea, although some persons who have given it a trial claim to have had an experience of this kind. I have so often described my own experience in the use of this drug that I will not repeat myself here. When the subject is too young to admit of the administration of pills, triturations may be employed.

No plan of treatment would be entirely satisfactory where an examination of the mouth and upper pharynx was neglected. Oral irritation may thus be found to consist in the eruption of teeth, caries of the teeth, irregularities, tartar, irritation from catarrh of the gums, periostitis and alveolar abscesses. The frequency of the occurrence of these conditions has been mentioned above; they require treatment and likewise often the assistance of the dentist. Under treatment the worst agonies of earache may be prevented, and very often our remedies act like a charm; but it must not be forgotten that the causes in a given case may not be so easily eradicated, and that treatment must be kept up for some time if we would entirely prevent a return of this tormenting disease. Catarrh and other affections of the naso-pharynx and Eustachian tubes also require like care, and sometimes must be treated actively.

The advantages of rest in acute purulent inflammation of the middle ear should never be lost sight of, and the patient should be kept indoors for several days. If the case be a severe one, he will be best off in bed for a time. Quiet ought to be maintained in all cases, for noises sometimes under these circumstances become exceedingly distressing. The evils of active treatment in these cases, by syringing, etc., have been alluded to, and it may here be urged that deafness as a symptom should not be treated; especially should inflation be avoided; the patient is to be cautioned even against violently blowing the nose. Of course in the later stages syringing and mopping may be more thoroughly practised and the cautious use of the air-douche may even be advisable. The well-known tendency of some drugs to cause or increase existing aural hyperæmia should warn us to avoid their indiscriminate use. First among these is quinine, which has long been suspected of causing deafness when administered in large doses in malarious diseases. The intense tinnitus aurium following its administration establishes the fact of an increased vascular action in and about the ear. The employment of ferruginous preparations seem to have a like effect, and doubtless there are many others which it were best to omit when the ear is inflamed.

During the existence of acute aural disease, the consequences of its early management upon the subsequent course and duration should be kept in mind, but the consideration of chronic processes here would lead me beyond the scope of the present paper, which has, I fear, already been unduly drawn out.

MAJALIS OR MAIALIS?—Dr. S. S. Wallian, of Bloomingdale, N. Y., asks for the authority upon which the spelling "maialis" is based. The spelling, according to Gray, is "convallaria majalis." It is so given by Webster. The use of "i" instead of "j" has no doubt been adopted because it is so spelled on the continent of Europe, and especially in France.

ON RAPID OR SUDDEN HEART-FAILURE IN ACUTE INFECTIOUS DISEASE, NOTABLY IN DIPHTHERIA AND TYPHOID FEVER.¹

By BEVERLY ROBINSON, M.D.,

NEW YORK. 1

FOR many years this subject has been one of peculiar interest to me. Already, when an assistant or house physician in the medical wards of a large city hospital, I had seen cases of this sort. They impressed me at the time, and gave me food for thought afterward. In the course and progress of chronic disease, too often do we see the heart become acutely embarrassed, even when no previous organic disturbance prevailed, and frequently a speedy and fatal termination closes the scene. But such instances, though painful to witness, do not specially command our attention, nor strike us even as remarkable. When a patient has been for a long while suffering from some severe chronic ailment, and his strength and vitality are evidently much impaired, that a complication should arise within the heart and occasion death, is what we have reason in a measure to expect, and if it occur not to be surprised. A like feeling may, indeed, prevail with respect to acute disease, especially if from the beginning it assumes a serious aspect, and proceeds surely from bad to worse. But there are numerous examples, and these are specially the ones we would dwell upon at some length, in which the disease has at no stage from the very beginning been of more than moderate intensity, and yet rapid or sudden death will occur, presumably due to the changes produced in the cardiac structure. Such cases are not new. Occasional reports of them may be met with in medical periodicals during many years in the past. And yet, so far as I know, they have never been considered collectively, nor has an entirely satisfactory explanation of their pathogeny been given, nor their therapeutic indications been made clear. To fill up in small degree this lacuna in practical medicine is the object of this paper.² Only one month ago, when visiting daily at St. Luke's Hospital, I had several cases of typhoid fever under my care. Amongst them, two patients presented grave symptoms throughout the duration of the disease. In one of these the fever lasted only two weeks, and at the end of this time death took place. Previous to the end there had been high temperature, marked nervous phenomena, and moderate diarrhœa. Finally, the lungs became much congested, the brain wandering, the pulse weak, rapid, and intermittent, the heart-sounds feeble, and the patient succumbed when she was extremely prostrated. An autopsy was not obtained.

In my second case, that of a young girl twenty-two years of age, a teacher, who had been under the care of Dr. Pallen some weeks before for intrapelvic cellulitis, there was evident malarial complication, which rendered the convalescence long and tedious. In this example the main cause for anxiety was referable to the heart. The temperature, with the exception of two or three passing exacerbations, was moderate during the continuance of the fever. There was little or no diarrhœa after the first week. No nervous complications arose, with the exception of great somnolence, due to congestion of the cerebral vessels, and the lungs remained intact, the respirations being always regular and of normal frequency; but the cardiac pulsations were, during three or four weeks from the time of entrance at St. Luke's (about fourteenth day of disease) extremely weak. They were clearly defined, however; there was no muffling, no abnormal bruits. Occasionally they were somewhat uneven and irregular, without perceptible intermissions. The pulse at the wrist was quite frequent, at times running up to one hundred and ten, one hundred and twenty,

¹ Read at a meeting of the Practitioners' Society, March 2, 1883.

² This was my object when I began this article *more than a year ago* (December 1, 1881), but circumstances have prevented my carrying out my intentions, and I now present it to the Practitioners' Society merely as a suggestive note in regard to an important and interesting matter of practical medicine.

or even one hundred and thirty pulsations; but wherein it was a source of solicitude was its extreme weakness. At times it was very depressible, thready, or completely disappeared under the palpation of my fingers exercising the most gentle pressure. This patient was treated with small and quite frequent doses of all the cardiac tonics—*nux*, *belladonna*, and *digitalis*. She had tonic doses of fluid extract of bark, stimulant in the form of brandy, as much as I considered proper to give, milk, meat extracts, raw or lightly boiled eggs, strong black coffee in doses of two ounces morning and afternoon, fluid extract of coca—in fact, my therapeutic armamentarium was exhausted in my efforts to raise this flickering life, and in the end I apparently succeeded, for my patient has now almost recovered and is walking about the wards. I say *apparently*, because for more than one week I could see no perceptible change in the patient's strength, and when she did show manifest improvement, I confess I was uncertain whether my medicines had occasioned it, or the disease, having reached its climax, had waned according to a natural law.

The third case to which I shall refer was one of which a short abstract will be found reported by me in the "Proceedings of the Pathological Society" for November 23, 1881. It was briefly as follows: The patient was a man thirty years of age who died suddenly during the progress of typhoid fever, at St. Luke's Hospital, on November 12, 1881. Death occurred on the nineteenth day of the disease. The patient's temperature had not been much elevated until the second day before his death, when it reached $103\frac{1}{2}^{\circ}$ F., and the pulse 120. Diarrhœa moderate in character. On November 9th and 10th he was delirious and weak; on the 11th semi-comatose, and on the 12th his breathing became very rapid without apparent cause; face and extremities not cyanosed, and he gradually sank and died at 9.15 A.M. At the autopsy there was enlarged and softened spleen, splenization of the lungs, fatty kidneys, swollen solitary follicles, and numerous ulcers scattered along the entire length of the ileum. The ileo-cæcal valve was thickened and extensively ulcerated. The feature of special interest was the existence of a long, slender, fibrinous clot attached to the aortic and mitral valves, and extending ribbon-like into the aorta. There was also an ante-mortem clot attached to the chordæ tendineæ. There was quite extensive granular degeneration of the muscular fibre of the heart.

Now then, to sum up these cases in a few words. With respect to the evidences of cardiac failure, we would remark, in the first case, that the other symptoms were such as to render the cardiac weakness only a part of the general portrait of the disease, which in this instance tended toward a fatal termination. In the second example the cardiac failure was considerable but not complete, and hence life held on, though trembling more than once in the balance. In the third and last example, although there were well-marked lesions at the autopsy of typhoid fever at the stage during which the patient died, yet the termination seems to me to be connected particularly with the condition of the heart. Some years ago, when a resident physician in a large children's hospital, I was called from my room to see a patient in the ward, a lad about twelve years old, convalescent from typhoid fever, who, while seated in bed and about to take a goblet from a shelf at the head of his bed and drink, suddenly became pale, fell back, and, without a struggle or any convulsive movement, immediately expired. In this example no sufficient explanation was afforded by the autopsy of the cause of death. There was no heart-clot, no pulmonary embolism, no evident degeneration of cardiac fibre, no alteration of the pulmonary structure. In the absence of recognizable cause, the heart was said to have been paralyzed and death the result. This, as you all admit, I am sure, was a lame and unsatisfactory conclusion. Such instances have in the last few years been connected with morbid alterations

in the pneumogastric nerves, or cardiac ganglia, when the muscular fibre has been shown under the microscope to be healthy in appearance—without granulations or fat-globules, and with the transverse striae well marked.

Instances of partial or complete heart-failure are even more frequent in diphtheria than they are in typhoid fever. In some of these cases where death has taken place within a few days of the inception of the disease, and where the extension and character of the false membranes in the fauces, the swollen condition of the infra-maxillary ganglia; the excessive pallor, or almost waxy hue of the integument; the somnolence and prostration of strength, all indicate a high degree of septicæmia—the heart may only share in the general downward march, and it is not noteworthy to emphasize especially the weakness, irregularity, or frequency of its beats, but occasionally, even with all the concomitant phenomena of gravest import, the cardiac action is relatively strong and but little impaired until a brief period, perhaps only a few hours, before the fatal termination. Such a case I attended with Dr. Morris J. Asch during the past winter (1881-82). The following is taken from notes kindly sent to me by Dr. Asch, with respect to our case:

Called to see Mrs. G— on October 15th. I found her with a red and swollen tonsil on the right side, and with some fever. The next day the tonsil was still inflamed, partially covered with a thin, gray film, and the uvula cedematous. The patient complained of dysphagia. Dr. Asch considered the case one of diphtheria. The next day there was swelling of the submaxillary glands, but the diphtheritic exudation was not extensive until a day or two later, when both tonsils, the uvula, and the whole of the soft palate were covered with a thick, gray membrane. At this stage I saw the patient in consultation with Dr. Asch. Two days afterward she died at 3.15 P.M. Dr. Asch saw her an hour and three-quarters before her death. At that time he found her in great distress and in a state of great weakness. "She sat up for me, however," he writes, "to spray her throat. When I left she was *bright*, though very weak. Her heart was beating feebly, and I urged the necessity of giving her stimulants at once. When I returned, at a little after three, she had just died. She had called her mother to her and given her a kiss, and expired. She died of asthenia." Dr. Asch adds, "There were no laryngeal symptoms, nor any pulmonary ones of a nature to have been looked on as serious. If the patient could have been tided over another day, I think the force of the disease would have been expended."

It will be understood from the above reading, and, in fact, it is so stated farther on in Dr. Asch's account, written to me at my request, that he considered this patient as having succumbed to intense *asthenia*. But what was the organ principally and fatally affected by the diphtheritic poison? Was it not clearly and indubitably the heart?

Still another case in which death took place this winter in a young married lady who had been a patient of mine, and whom I had cared for when the diphtheritic membrane first showed itself on her tonsils. At that time she was passing a few days in New York, and staying at one of our large city hotels. When I saw her at the hotel, and after careful examination of her throat, I urged her immediate removal to her home on Staten Island, where she was afterward under the professional care of Dr. Frederic Clarke, and also saw Dr. Austin Flint, Sr., in consultation. The following very interesting, graphic description of this patient was sent to me at my request by Dr. Clarke after her death. I take the liberty of narrating it in extenso: "I first saw Mrs. W—, Wednesday, November 2, 1881, and found her with a rapid, full pulse, face flushed, and a well-marked diphtheritic exudation on both tonsils, which rapidly extended in every direction. She did fairly well for the first six days, pulse strong and regular, with no dyspnoea or thoracic oppression. On the following

Wednesday, in my presence, she suddenly complained of pain in the precordial region, about over the valves of the pulmonary artery, and her face, which all along had been (with the exception of the first day) perfectly natural in expression and color, suddenly became of well-marked leaden hue, accompanied with a very distressed look, with some oppression; pulse weak, regular, and about 96, and she several times said she was choking. These symptoms soon passed over, and she was moderately comfortable until Friday last, but with a persistently weak pulse. About 11 o'clock, Friday, A.M., she was seized again with precisely the same symptoms, which were longer in yielding to remedies. In the evening she was bright, expression and color of face good, with pulse at 80 and regular, but *very weak*. Passed a fair night, not restless nor inclined to throw herself about the bed. She expired Saturday, 7.30 A.M., *very suddenly*, without any previous exertion, lying quietly on her back. At no time could I detect anything abnormal about heart or lungs. Signed, F. E. Clarke."

I may add that I was informed later by a sister of this lady that Dr. Austin Flint, Sr., saw her the evening before she died, and did not think at that time that there was any occasion for special anxiety with respect to the cardiac condition. Dr. Clarke, I am told, considered the complication which caused death directly to be the formation of an intra-cardiac thrombus. No autopsy was made.

In regard to cases of diphtheria and typhoid fever I will at once direct attention to the following observations, which I have time and again corroborated and verified in the dead-house: There is a marked difference in the condition of the heart of a patient dying of typhoid fever and of one dying of diphtheria. Although apparently similar in character, I have found the right heart ventricle and auricle in diphtheritic patients filled, as a rule, with a mass of fibrinous deposit, which seemed to have been formed some days prior to death. In several cases of death from typhoid fever, I have found the blood in the right heart liquid, and in the left heart coagulated fibrinous masses of small dimensions, which did not seem, however, to be the immediate cause of death.

The last case to which I would direct attention is the following: Somewhat more than one year ago I saw, in consultation with my friend Dr. F. H. Bosworth, a boy about five or six years of age who was suffering from diphtheritic laryngitis. The dyspnoea became so intense as to render tracheotomy necessary. During the night following the operation the tube became blocked up with blood and false membrane and threatened immediate suffocation. A young man, in this emergency, who was boarding in the house, applied his mouth to the tube and attempted by forcible suction to free it of its obstruction. A few days later this gentleman was taken ill with diphtheritic angina. The case was one of moderate severity and progressed favorably from day to day. The membranous deposit, after several days' duration, had in great part disappeared from both tonsils, and the patient, who was naturally a strong, robust man of twenty-five to thirty years, was seated in bed and well enough to be playing a game of cards with his nurse, so as to lessen the tedium of his forced confinement. Suddenly, without premonitory symptoms, he complained of a distressed feeling in the precordial region, became pale, his extremities cold, scarcely perceptible pulse at the wrist, and he fell back on his pillow in a synopal state of very alarming character. The nurse at once used all ordinary means (friction with mustard, hot bottles to feet and trunk, exhibition of considerable amount of brandy, etc.) to restore consciousness and vitality. After about three-quarters of an hour her endeavor was rewarded by seeing a manifest change for the better in her patient. I arrived shortly afterward, only to hear the detailed history of the accident and to recognize no sufficient cause in the heart or pulse to explain the symptoms which had taken place.

The patient continued to do well when, under analogous circumstances, three days later, the same occurrences were again remarked. On this occasion Dr. Austin Flint, Sr., was sent for at the same time as myself. Dr. Flint saw the case with me about one hour after the termination of the phenomena of the second attack. At this time auscultation of the heart revealed *absolutely* nothing abnormal, and palpation of the pulse showed it to be regular and of tolerably good volume. From this time onward the patient continued to make a good recovery, without intercurrent complication of any sort.

The explanation of the sudden cardiac failure in this and similar cases is difficult to give in a thoroughly satisfactory manner. In some, undoubtedly, cardiac thrombosis is the immediate cause. But whether in these instances the blood stagnates and finally forms coagula in the right heart, owing to a relative increase of fibrin, or because the cardiac contractile force is rapidly diminished and thus makes a predisposing condition of fibrinous deposit, it is very difficult positively to affirm. In certain examples where death has followed in diphtheria within a few days of the beginning of the attack, I have noticed a condition of granulo fatty degeneration of the muscular fibres. But even in these instances, and with a considerable knowledge of this subject, I do not recognize a morbid change more advanced than one finds in the majority of cases of acute febrile disease which terminate by death due to other causes. The pneumogastric trunks and the peripheral fibres, as well as the intra-cardiac ganglia, have been more than once examined carefully in such examples, without leading to the discovery of a change of structure sufficient in amount to account for the rapid and fatal issue. I am disposed to-day, in view of what I have been able to remark at the bedside, to recognize the fact that at times—not infrequently, in fact—there is a *sudden and considerable dilatation of the cardiac cavities, and especially of the right heart*.

Coagula may form under these circumstances, or, if the heart be immediately and strongly stimulated, the imminent stage may be tided over and only incomplete failure, with dangerous but not fatal symptoms, occur. The fact of the existence or non-existence, at the autopsy, of the coagulum in the right or left heart, which may also be of larger or smaller size, and of more or less consistence, is, doubtless, explained by the intimate blood condition which an advanced physiological chemistry can alone satisfactorily elucidate. In regard to the therapeutic indications, and as at present advised, they are few and simple.

First.—All unnecessary fatigue should be absolutely avoided during the duration of even the mild cases of diphtheria and typhoid fever. Patients should not be permitted to raise themselves in bed, to sit up but a very short while on any particular occasion, and then only when convalescence is well advanced. They should not be allowed to feed themselves or to perform any act which causes outlay of physical energy and which can be avoided by judicious nursing.

Second.—Cardiac tonics should be employed in *very moderate* doses from a relatively early stage of the disease, and particularly if there be even slight manifestations of cardiac failure, as shown by inequality or irregularity in force or rhythm of cardiac beats, or of the radial pulse, or indeed, by attacks in any manner resembling those to which I have referred.

Third.—In typhoid fever, as well as in diphtheria, I look upon black coffee as a very valuable stimulant, and therefore particularly urge its employment early in the course of the disease. Besides the above recommendations, I naturally incline strongly to the use of liquid nutriment in very concentrated forms. In regard to one drug so largely used by the medical profession generally, in the treatment of asthenic forms of acute disease, I am disposed to enter here a word of warning—and it is about the internal use of large doses of the tincture of the chloride of iron. This tincture is one of the most power-

ful styptics and astringents we possess, and is presumed to exercise these properties in the blood if it be absorbed. Now, then, to what extent, I have already asked myself on more than one occasion, is it responsible for the formation of intra-cardiac fibrinous coagula, particularly in diphtheria?

I here leave the very important subject presented in this paper for full consideration by the members of our society.

FOUR CASES OF OPIUM-POISONING.

TREATMENT BY ATROPIA AND THE FARADIC CURRENT —RECOVERY.

By SAMUEL S. WALLIAN, M.D.,

[BLOOMINGDALE, N. Y.]

APRIL 3, 1883, four men, J. W. L.—, C. C. T.—, A. B.—, and S. L. P.—, jointly drank from a bottle (supposed to contain whiskey and quinine) four ounces of tincture of opium (Phar. of 1870). Nearly half an hour elapsed before the nature of the mistake was fully realized.

By this time Dr. Rice and myself were both summoned. He, being nearer, arrived some minutes first, and very soon administered to each a very large dose of sulph. zinc, in solution, to which was added fifteen grains of ipecac. On my arrival he was mixing a second dose of the same, which was promptly swallowed by three of the unfortunates, without effect, save in the case of S. L. P.—, who vomited slightly. Advising further efforts at producing emesis by irritating the fauces, etc., I sent for my buggy case, which was at some distance, and after three of the victims had called for and swallowed a third large dose of the zinc and ipecac, I hastily prepared a solution of apomorphia mur.; and, as the impending narcosis was not yet perceptible in any one of the cases, I risked the injection of one-sixth grain subcutaneously into the arms of each. My anxiety lest this drug should also fail to procure emesis, in which case it would necessarily add to the approaching narcosis, was quickly dispelled. Within three minutes emesis was quite free with two, and moderately so with the other two.

Copious draughts of warm mustard and water were supplied, but it was soon evident that no further emetic effects could be secured. It was now 5.30 P.M., the poison having been swallowed not far from four o'clock.

Five grains citrate of caffeine were exhibited to each of the four, and ambulation resorted to vigorously.

Asking the druggist, from whom the drug had been—without fault of his—procured, to give me, as nearly as possible, the equivalent in morphia received by each patient, which he stated to be $4\frac{1}{2}$ grains, I prepared a solution of atropia, gr. j. to 3 ij., of which I injected, subcutaneously, ℥xij. (= gr. $\frac{1}{10}$) to each patient.

In case of A. B.—, who vomited a little earlier and more freely than the rest, complete narcotism did not ensue, and ambulation was kept up without great effort.

By 7 P.M. I repeated the dose of atropia, gr. $\frac{1}{10}$. Seeing no apparent effect from the two doses, aggregating $\frac{2}{10}$ gr. to each patient, and recalling the antagonistic ratio existing between atropia and morphia, as stated by Bartholow, viz., atropia, gr. ss. to morphia, gr. j., I prepared a solution double the strength of the former one, or, grs. ij. to 3 ij. Of this I exhibited ℥xxiv., hypodermically (= gr. $\frac{1}{10}$), to each of the three most under the influence of the narcotic. By this time—7.30—the pupils of the latter were contracted to a mere dot, narcosis was so fully established that they could not be roused by the most vigorous measures, and ambulation was entirely out of the question.

Respirations fell to 8 per minute; the pulses of all became fainter and slower until scarcely perceptible. Having sent for my battery I now applied a strong faradic current, one pole over the diaphragm and one at the nape of the neck. By carefully interrupting the current

at regular intervals respiration was gradually restored, but in each case the application had to be repeated as often as every ten minutes. Twice in the cases of J. W. L.— and C. C. T.— respiration was suspended for a space of two minutes each time, and the struggle seemed to the assistants to have become a forlorn hope. Gradually the antagonistic influence of the atropia began to assert itself; the pupils gradually relaxed, and by 9.30 P.M. the respirations were quite regular and $10\frac{1}{2}$ to 11 per minute. The three were now lying in a tranquil sleep, from which, however, they could not be roused by any effort. By 10 P.M. S. L. P.— showed signs of returning consciousness, swallowed some stimulants, and could be momentarily aroused. Pupils of all well dilated; respirations, easy and regular, 11 to 14 per minute; pulses, 70 to 95.

We now had all removed to more comfortable quarters, the two more fortunate subjects walking between two assistants.

Warmth was now applied more effectually than before—in fact, too zealously by some of the excited assistants, as some severe hot-bottle blisters abundantly testify!—but with the exception of occasional sips of brandy and ammonia, with beef-juice, no further treatment was deemed necessary. To the two who were already convalescent, milk and other nourishment were freely allowed.

By 4 A.M. it was evident that all were out of danger.

The effects of the antagonist, atropia, were visible for forty-eight hours or more, as shown by disturbance of vision, unsteady gait, hallucinations, harmless delirium, etc., which would seem to indicate that it was exhibited somewhat in excess of the requirements in the several cases.

Impossible as it was to estimate accurately just how much of the laudanum had been ingested by each, and how much ejected by emesis, this result was unavoidable.

I now think it would have sufficed had the third dose been limited to $\frac{1}{10}$, or even to $\frac{1}{20}$, gr.; yet Bartholow, as stated, and other good authorities, insist that it requires $\frac{1}{2}$ gr. atropia to antagonize one gr. of morphia.

If we assume, on their own and the druggist's subsequent statements, that the two worst cases received the equivalent of five to six grains of morphia each, and also assume that only one-third of this amount was ejected by the delayed and imperfect emesis, about four grains would require to be antagonized in each case. This, according to the authority quoted, would require two grains of atropia. The inference is, that not more than $\frac{1}{10}$ grain, and perhaps even $\frac{1}{20}$ grain, of atropia is sufficient to antagonize one grain of morphia.

No doubt the prompt use of apomorphia at a critical moment, the after administration of caffeine, and the vigorous application of the faradic current, contributed something to the success of the treatment; but it is evident that but for the timely use of atropia all other means would have failed to save life in at least two of the four cases.

HOT WATER IN THERAPEUTICS.—Several years ago I learned in my personal experience that no agent relieves nausea and vomiting so satisfactorily and promptly as water, as hot as can be drunk. Since then I have used it in a large number of cases, and it has been uniformly reliable. The following classification may be made of the cases in which it has been used: 1, Cases in which nausea and vomiting occurred at the outset, or during the course of acute febrile disease; 2, cases in which these symptoms were caused by overloading the stomach when its functions had been impaired by protracted disease; 3, cases in which they were produced by nauseous medicines (not emetics), at the time they were taken; 4, cases of acute gastritis, caused by the ingestion of irritants; 5, cases in which these symptoms were purely reflex; 6, cases of chronic gastritis; 7, cases of colic in newly born infants; 8, cases of flatulent distention of the stomach.—DR. DOUGLAS MORTON.

Progress of Medical Science.

REMOVAL OF CARIOUS PORTIONS OF THE VERTEBRAL BODIES.—Dr. Boeckel relates the history of a case in which he removed the carious portion of the bodies of two dorsal vertebrae, by means of the sharp spoon, with gratifying results. From his experience in this case and in operations upon the cadaver, the writer concludes that it is not so difficult as is usually supposed to reach the anterior portion of the spinal column. The resection of an inch to an inch and a half of one rib affords room enough for the finger to reach the bodies of the diseased vertebrae. The danger of wounding any of the great vessels lying in front of the spinal column is not so great as it seems, as the pus has already formed a sinus which serves as a guide to the diseased bone. The bodies of the lumbar vertebrae may be reached by an incision made at the outer border of the sacro-lumbalis muscle, as for nephrotomy. The same operation is indicated in gunshot wounds of the vertebral bodies. The difficulty in such cases lies less in the operation itself than in the uncertainty of the diagnosis respecting the location and extent of the injury to the bone.—*Schmidt's Jahrbücher*, March 14, 1883.

TRAUMATIC PARALYSIS OF THE QUADRICEPS MUSCLE.—Professor Lücke states that slight injuries sometimes cause a loss of function with rapid atrophy of the quadriceps extensor femoris. The electrical irritability is markedly diminished but never entirely lost. A passive effusion into the knee-joint occurs from relaxation of the capsule. In a similar affection of the deltoid there results, from loss of support, an apparent luxation. The author believes that many cases of so-called congenital dislocation of the hip are due to a like condition which obtains in the muscles about the hip. The prognosis of traumatic muscular atrophy when untreated is bad. But treatment, if undertaken early, is very successful. It consists in the application of a weak constant current at first, and the induced current later.—*Centralblatt für Chirurgie*, February 24, 1883.

UMBILICAL HERNIA OF A PART OF THE STOMACH-WALL.—A boy, thirteen years of age, had a tumor, about the size of a walnut and of a bright red color, at the navel. It was covered with mucous membrane, which secreted, upon being handled, a viscid fluid of acid reaction. The tumor, which was attached to the umbilical ring by a slender pedicle, remained always of the same size and was irreducible. No opening into the interior could be discovered. The mother stated that the cord had been of great thickness, and, near the navel, was funnel-shaped. It was ligated very close to the body. When the end came away the tumor was noticed. There had never been any food or fecal matters discharged from the navel, nor did the secreted mucus ever have a fecal odor. The pedicle was cut through, and the wound rapidly cicatrized. Dr. Tillmanns, who reported the case (*Centralblatt für Chirurgie*, March 3, 1883), believed it to be an ectopia ventriculi. He stated that the secretion possessed the power to digest fibrin, and further, the microscopical examination of the tumor showed it to be composed of gastric mucous membrane from the neighborhood of the pylorus. The portion of prolapsed stomach was cut off with the umbilical cord, this little piece being at the distal end. The opening into the stomach was closed probably at the time of birth.

TETANUS HYDROPHOBICUS.—The following case of a peculiar affection, first described by Rose, is related by Dr. Von Wahl (*Centralblatt für Chirurgie*, January 6, 1883). A man, forty-one years of age, while intoxicated fell down some steps, striking his forehead just above the right orbit. Very extensive ecchymosis of the right cheek followed. At the end of a week the patient felt

well, but on the ninth day lockjaw set in, there was right facial paralysis, and the right eye could not be closed. The left eye, on the contrary, was spasmodically shut, the teeth were pressed firmly together, and the muscles of the cheek, even on the paralyzed side, were as hard as a board. The sensibility of the skin on the right side of the face was somewhat diminished. The movements of the head were at this time perfectly free. On the following day it was necessary to perform tracheotomy on account of dyspnea, and on the day after that spasm of the right trapezius muscle appeared. The pupils at first responded slowly to light, but were now strongly contracted. The patient died of pneumonia. At the autopsy, the right vertebral artery was seen to be considerably smaller than the left; the right half of the pons was also smaller than the left, while the pyramidal and olivary bodies on the right side appeared broader and fuller than those on the left. There was no lesion (abscess or tumor) of the pons. There was no fracture of the cranial bones nor injury of the cranial nerves.

FEVER DEPENDENT UPON FECAL ACCUMULATION.—A rise of temperature is often observed in women after childbirth or ovariectomy, which subsides after a free movement of the bowels. In addition to the fever there are frequently symptoms of peritoneal irritation—pain on pressure, meteorism, elevation of the diaphragm, cyanosis, and rapid pulse. To explain these symptoms, Dr. Küstner instituted a series of observations upon women after ovariectomy (*Zeitschrift für klin. Medicin*, vol. v.). He found that the temperature rose when the fecal matters had passed into and distended the rectum. By reason of increased peristalsis and from direct pressure of the distended rectum, the wounded surfaces were disturbed and a resorption of the secretions induced. This gave rise to fever. Perhaps also the retained feces caused a more rapid decomposition of the secretions. The same explanation will answer also for similar conditions in the puerperal state, and the author asserts that peri-uterine exudations are often due to the same cause.

THE TUBERCULAR NATURE OF DIABETIC PHTHISIS.—Drs. Immermann and Rüttimeyer report in the *Centralblatt für klinische Medicin*, of February 24, 1883, a case of phthisis in a diabetic subject, in which tubercle bacilli were found in the lung-cavities. Though convinced of the tubercular nature of that particular case, they are not prepared to formulate general conclusions from one observation. They state, however, very truly, that the more often tubercle bacilli are found in the lungs or sputum in similar cases, the more certainly will the etiological identity of diabetic phthisis and ordinary pulmonary phthisis be established. And further, the more certainly the tubercular nature of diabetic phthisis is proven, just so certainly will the greater frequency of phthisis in the subjects of diabetes demonstrate that the constitutional conditions in this disease are favorable for the reception and development of the parasite.

A SIMPLE METHOD OF PRODUCING LOCAL ANÆSTHESIA.—Dr. Cheize relates (*Moniteur de la Polyclinique*, March 25, 1883) a simple procedure adopted by him in a case of ingrowing toe-nail, requiring immediate operation, at a time when he had no apparatus at hand. He saturated a little piece of lint with ether and placed it on the toe. He then projected the air from an ordinary pair of hand bellows upon the lint until the ether was evaporated. This was repeated two or three times, when anaesthesia was so complete that the nail was removed without the patient's knowledge.

INFLUENCE OF ANEMIA ON THE ELECTRICAL IRRITABILITY OF THE CEREBRUM.—From a series of experiments upon dogs, conducted in Munk's laboratory in Berlin, Dr. Orschansky formulates the following conclusions: 1. The abstraction of less than one-seventh of the total volume of blood of the animal does not modify

the excitability of the psychomotor centres of the cerebrum. 2. The loss of one-seventh to one-fifth of the entire volume of blood increases the irritability. The abstraction of a greater quantity causes a gradual diminution of excitability until it is finally lost completely. At the same time there is a flattening of the convolutions and the pulsations of the brain cease. 3. During the period of increased irritability, the animal is restless and agitated. As the irritability is lessened he becomes quasi-narcotized, though the power of voluntary movement remains. 4. These changes are not dependent upon the lowered blood-pressure. 5. They are caused by the induced anemia, which seems to act through lowered nutrition of the brain.—*Deutsche Medizinische Zeitung*, February 8, 1883.

CONSTITUTIONAL TREATMENT OF CHRONIC UTERINE DISEASE.—A forcible plea in behalf of constitutional measures in the treatment of chronic womb troubles is entered by Dr. Boislinière in the *St. Louis Courier of Medicine*, April, 1883. He concludes his paper by the following practical suggestions:

"The late excessive tendency to specialize has led us to attach, in uterine affections, too great an importance to the lesions and not enough to the general condition. The morbid influence of the constitution on the uterus should be considered first, and the reciprocal influence of the uterus on the organism should be considered as secondary. The uterus does not lead an isolated life in the organism, but it is only a link in that harmonious chain constituted by all the organs, and if the action of that chain be disturbed, there will be suffering in every organ constituting the chain. There will be suffering in the uterus, as well as in any other organ, but not more."

OPERATIONS FOR CATARACT IN THE SUBJECTS OF CHRONIC DISEASE.—Dr. Armaignac opposes the commonly entertained opinion that operative measures should be avoided in cataract occurring in individuals suffering from any cachexia. He has examined the records of a number of operations for the cure of cataract performed in his clinic, and he states that he has yet to meet with a failure in patients suffering from either diabetes, albuminuria, cancer, or malaria. In every case the cure was at least as rapid as it is usually in healthy subjects, and it occurred without inflammatory reaction or complication of any sort. Some of the operations were performed in the last stages of the general affection.—*Revue Médicale*, March 17, 1883.

ADDISON'S DISEASE AND THE SUPRARENAL CAPSULES.—From a study of the literature bearing upon this subject, Dr. Carl Burger arrives at the following conclusions: The suprarenal capsules are, from their structure, to be classed among the blood-vascular glands, and have no important vital function to perform. They stand in no causal relation to the bronzing of the skin. This dark-coloring of the skin occurs not only in Addison's disease, but may accompany a variety of cachexiæ. Disease of the suprarenal capsules is not infrequent, and often runs its course without any of the recognized symptoms of Addison's disease. The greatest variety of lesions of the capsules may be seen in different cases of Addison's disease. Addison's disease depends upon an affection of the semilunar ganglia and of the solar plexus. This affection is usually caused by some disease of the suprarenal capsules, most frequently a tubercular inflammation. Disease of the semilunar ganglia and solar plexus may arise from lesions of other organs than the suprarenal capsules, or may even be idiopathic. The symptoms of Addison's disease may thus be present without any lesion of the suprarenal capsules.—*Allgem. Med. Central-Zeitung*, March 14, 1883.

GLYCOSURIA AFTER REMOVAL OF THE MAMMÆ.—M. Paul Bert related, at a recent meeting of the Société de Biologie, the effects produced by the ablation of the

mammæ of a pregnant goat. After the birth of the kid, the urine of the goat was found to contain a very considerable amount of sugar. Owing to irritation, caused by vain attempts of the kid to suck, a large phlegmon arose in that region. The sugar at once disappeared from the urine. Similar experiments made about the same time, by MM. Bert and De Sinéty, upon pregnant guinea-pigs, were attended with negative results.—*Gazette des Hôpitaux*, March 20, 1883.

EFFECTS OF THE INTERNAL ADMINISTRATION OF GLYCERINE.—Dr. Tisné speaks highly of glycerine as a therapeutic agent internally administered. He states (*Gazette des Hôpitaux*, March 17, 1883) that it causes no irritation to the mucous membrane of the digestive tract beyond exciting a slightly increased peristaltic movement. It exerts a beneficial effect upon nutrition, increasing the weight and palliating many of the distressing symptoms in phthisis, such as loss of appetite, diarrhœa, night-sweats, and insomnia. Its action upon the liver is manifested by an increase in size of the organ and by a more abundant flow of bile. It has a diuretic effect and increases the excretion of urea, the chlorides, and the phosphates. The alkalinity of the urine is diminished, and if any pus be present in this fluid it is greatly lessened in amount.

ECLAMPSIA NUTANS.—Dr. Gantiez relates a case of salama convulsions which he witnessed in a child, seventeen months old. The attacks were preceded by a period, varying from a few seconds to a minute, during which the child presented an absorbed air, seeming to be a little apprehensive, but not agitated. The eyes were raised and fixed, and there was a little pallor. Then suddenly any toy that was in the hand was cast away, the head was flexed upon the thorax and the trunk upon the pelvis. At the same time the shoulders were slightly raised and the arms thrown forward with the hands extended, as if to prevent a fall. These movements followed each other with great rapidity, sometimes as often as thirty times in succession, but usually only eight or ten times. After the attack the eyes were filled with tears, and there was an expression of astonishment upon the child's countenance. He was easily comforted and soon resumed his play. The attacks occurred about eight times a day, and since they began, at the age of nine months, had never missed a day. Bromide of potassium had failed to exert any controlling influence over the disease.—*Revue Médicale*, March 3, 1883.

PUERPERAL INFECTION THROUGH EROSION OF THE NIPPLES.—The possibility of septic infection through wounds of the nipples, as well as through wounds of the genital apparatus, has hitherto received but scant notice. Professor Kaltenbach regards this occurrence as probable, arguing from the etiological relation between erosions of the nipple and mastitis, and from the beneficial effects claimed by Hausmann to follow the treatment of the fissures by carbolic acid. Spiegelberg has shown the possibility of mastitis arising from infection through the nipples and openings of the lacteal ducts. Kaltenbach goes further, and regards every case of mastitis as of septic origin. The necessity of the greatest possible cleanliness of the mouth of the child, the hands of the nurse, and the nipple itself is self-evident.—*Deutsche Med. Zeitung*, March 1, 1883.

INFLUENCE OF ERYSIPELAS UPON SYPHILIS.—Dr. Strack relates several cases in which the disappearance of gummy tumors was promoted by an intercurrent attack of erysipelas. He thinks this beneficial influence is exerted in two ways. The first effect is that which erysipelas exerts in common with other acute fevers. The second is to be referred to the local inflammatory processes. The increased flow of blood to the diseased parts causes a breaking down of the cell-infiltration, which becomes thus more readily absorbed.—*Centralblatt für Klin. Medicine*, March 3, 1883.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 5, 1883.

ELIGIBILITY OF DELEGATES TO REGISTRATION AT THE NEXT MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

At the last meeting of the New York Academy of Medicine the following unqualified statement was made:

"The New York Academy of Medicine is the only chartered medical society in the State of New York, which is entitled, through its delegates, to recognition, either in the American Medical Association or in any of the State Medical Societies in the Union. I wish that fact to stand fully before the mind of every Fellow of the Academy." (See report of the proceedings in *THE MEDICAL RECORD* for April 28, 1883, p. 472.)

There is a legal aspect of this statement which should not be entirely overlooked.

In the plan of organization of the Association it is stated that members shall hold their appointment either as delegates, members by invitation, or as permanent members. "The *delegates* shall receive their appointment from permanently organized State Medical Societies, and such county and district medical societies *as are recognized by representation in their respective State Medical Societies*, and from the Medical Department of the Army and Navy of the United States, and the Marine Hospital Service of the United States." ("Transactions American Medical Association," vol. 33, p. 618.)

Manifestly this clause means that only such county and district medical societies are entitled to representation in the association as are entitled to representation in their respective State Medical Societies. It is equally evident that the county and district medical societies stand upon the same level; that no privileges are granted to the one which are not extended to the other; and that the basis of representation exists in the words "entitled to representation in their respective State Societies."

According to this interpretation of the clause regulating membership in the American Medical Association, the societies in the State of New York, prior to 1882, entitled to representation in the Association, were the Medical Society of the State of New York, and the several county societies, together with the district medical societies which were entitled to representation in the State Medical Society.

There is only one medical society in this State which belongs to the class denominated district medical societies, and entitled to representation in the State Medical Society, namely, the New York Academy of Medicine.

This medical society derives its right of representation, by delegates, in the American Medical Association solely from the fact that it is entitled to representation by delegates in the Medical Society of the State of New York. The only relation which the New York Academy of Medicine sustains to the American Medical Association is that of a district medical society. It stands upon the same level, in that respect, with the county medical societies, and in common with them obtains the right of representation in the American Medical Association by the fact that both are entitled to send delegates to the State Medical Society. The statement then, that "the New York Academy of Medicine which has no connection with the State Society, except that it is empowered to send delegates to that body," does not unfold the close relationship existing between these two bodies and reveal the real dependence which the former has upon the latter with reference to representation by delegates in the National Association.

The question now arises, what are the conditions which exclude representation in the American Medical Association? These are found in Article IX. of the By-Laws, which reads as follows: "No State or local medical society, or other organized institution, shall be entitled to representation in this Association that has not adopted its Code of Ethics; or that has intentionally violated or disregarded any article or clause of the same" ("Transactions American Medical Association," volume 33, page 629). In the light of the clause in the plan of organization, already quoted, it is plain that the following interpretation of the above by-law must be admitted. No State or local medical society, or other organized institution—that is, no State, county, or district medical society—shall be entitled to representation in this Association that has not adopted its Code of Ethics; or, that has intentionally violated or disregarded any article or clause of the same.

This interpretation is sustained by the decision of the Judicial Council, at the last annual meeting of the American Medical Association, touching the action of the Medical Society of the State of New York in 1882, which says: "Having fully examined the Code of Ethics adopted by the New York State Medical Society at its annual meeting in February, 1882 [as furnished by the Secretary of said Society], the Judicial Council find in said Code provisions essentially different from, and in conflict with the Code of Ethics of this Association, and therefore, in accordance with the ninth by-law of the American Medical Association, they unanimously decide that said New York State Medical Society is not entitled to representation by delegates in this Association" ("Transactions American Medical Association," vol. 33, page 60). Accordingly, at the annual meeting of the Association, held at St. Paul in 1882, the delegates from the Medical Society of the State of New York were refused admission; but the delegates from the several county medical societies and the district medical society (the New York Academy of Medicine) were not excluded and were permitted to register. The legitimate inference is that they were permitted to register and become members of the Association because there was no evidence that the several societies which they represented had not adopted the Code of Ethics of the American

Medical Association, or had intentionally violated or disregarded any article or clause of the same.

If this be the true inference, we may still infer that those county societies and district medical societies which have adopted the Code of Ethics of the American Medical Association, and have not intentionally violated or disregarded any article or clause of the same, are yet entitled to representation in that body.

It has been said, and the inference was allowed among the members at the meeting at St. Paul, that the delegates from the county societies and the district medical society of the State of New York were admitted merely *as a matter of policy*, believing that the action of this State Medical Society would be repealed at the annual meeting in February, 1883. We do not believe, however, that the Judicial Council is a body that has been, nor will be, governed in its decisions by policy when the policy conflicts with the laws of the Association.

It is a matter of fact that all the county medical societies in the State adopted the Code of Ethics of the American Medical Association, and it is also a matter of fact, that only a very few have modified their by-laws in this respect, so as to make them conform to the system of Medical Ethics of the Medical Society of the State of New York. Indeed, a large number of the county medical societies have done more than has been done by the New York Academy of Medicine even, and have shown their hostility to the new Code, as it is called, by instructing their delegates to vote for its repeal, and for the re-enactment of the old Code. Why should not they be entitled to representation in the American Medical Association as well as the New York Academy of Medicine, whose delegates have, with a single exception, uniformly voted either for the new Code or against resolutions which provided for the re-enactment of the old Code? What has lifted this medical society into the elevated position among its peers in which some of its Fellows have sought to place it? There are, possibly, special reasons.

If policy or expediency is to govern the decision of the Judicial Council, certainly the delegates from the county medical societies and the district medical society will be received at the forthcoming meeting of the American Medical Association, the same as they were last year. For, the same argument, on the policy side, holds now as it did in 1882, namely, that the question *is not yet settled* in the Medical Society of the State of New York, because an amendment to the by-laws will be called up for action at the Annual Meeting in 1884, and if adopted, will repeal the action taken in 1882 and sustained in 1883, and besides, the opposition to the new Code is much more formidable and determined than it ever has been.

From the policy standpoint, therefore, we fail to see that the New York Academy of Medicine is the only medical society in this State entitled to representation in the American Medical Association. But it may be said that because the county medical societies are in affiliation with the State Medical Society, they are bound to make their by-laws conform with those of the State Medical Society, and are therefore cut off from representation. This is an argument, however, which those who believe that the New York Academy of Medicine

is the only medical body in the State entitled to representation, by delegates, in the American Medical Association, cannot safely employ. It proves too much. For, if it be true that the county and district medical societies are cut off from representation in the American Medical Association, by reason of the action of the State Medical Society, then is the New York Academy of Medicine cut off as certainly, because, without reference to its disavowals, it has been, and is now, in affiliation with the Medical Society of the State of New York. It has sent its delegates to the State Medical Society, has taken no action looking toward their withdrawal, depends upon the State Medical Society for its right of representation in the American Medical Association, has failed to even attempt to instruct its delegates to vote for the re-enactment of the old Code, and therefore its delegates should not be received if the delegates from county medical societies are refused admission.

A CITY OF DISPENSARIES.

THE subject of the abuses connected with medical charities in Philadelphia was made the subject of a paper and discussion before the Philadelphia County Medical Society, recently. Dr. J. W. Walk, who read the paper, said that there were in Philadelphia thirty-two free dispensaries, which treated in one year 161,019 cases, or about one-fifth of the entire population. Dr. Walk was disposed to think that the dispensary system was a pernicious one, injuring both the profession and the public. He referred to a previous attempt to secure reform made three years ago, and which had proved futile. There had recently been organized a "provident dispensary," modelled after the institutions in London. It remained to be seen whether this would turn out a success.

The statement of Dr. Walk's, that Philadelphia has thirty-two dispensaries, is a surprising one. It places Philadelphia at once at the head of all the cities in the Union in the matter of these institutions. New York City, with a population one-third greater, has only twenty-two, and many of these do very little work. Nine dispensaries in this city treat nine-tenths of the patients. On the other hand the actual amount of free dispensary service is about the same for both cities. In New York, a quarter of a million of persons are treated at the dispensaries annually, which is one-fifth of our population.

There are many abuses connected with this form of charity and we trust that Philadelphia will be able to inaugurate some effectual measure of reform.

PAINFUL CONGESTION OF THE LIVER IN THE EARLY STAGES OF ALCOHOLISM.

BUT little has been written concerning the early stages of hepatic disease in hard drinkers. The symptoms at this time are insignificant, or, at any rate, are not troublesome enough to disturb the equanimity of persons that are not habitually solicitous about their health. Dr. Mathieu was led to examine the liver carefully in a number of patients who already presented some of the early signs of alcoholism. In no instance were there any subjective symptoms of hepatic disorder, yet there was always an in-

crease of liver dulness of about one inch above the normal. There was at the same time some tenderness on pressure. In the majority of cases examined there was also a slight enlargement of the spleen. The author regards this enlargement, combined with tenderness on pressure, as indicative of a congestion bordering on inflammation. It will, in time, pass into true inflammation, which may, according to circumstances, assume the form of general hepatitis, or of one of the varieties of cirrhosis.

THE ETIOLOGY OF PERNICIOUS ANÆMIA.

PROFESSOR FRANKENHÄUSER has made the rather startling discovery that pernicious anæmia is caused by bad teeth. He claims to have found in the blood of pregnant women suffering from pernicious anæmia little, round, very active bodies, about one-tenth the diameter of a blood-corpuscle, and furnished with a scarcely discernible tail. Besides these there were other objects, longer than the preceding, without tails and more sluggish, which seemed to be in a state of transition into double-celled bodies. The smaller bodies were exceedingly active, resembling spermatozoa in their rapid movements. As he never found these micrococci in the blood of pregnant women not the subjects of pernicious anæmia, it seemed to the author most reasonable to conclude that there was some connection between them and the disease. The next question to determine was in what way these little strangers found entrance into the blood. The most promising field for investigation was now the liver, an organ which he had for a long time regarded, on clinical grounds, as the disease centre. And the investigator was not disappointed, for he found in the liver-cells, near the left lobe, in severe cases of the disease, a great number of multicelled filaments. These, he thought probable, had worked their way from the intestine up through the ductus choledochus and biliary ducts into the liver-cells. Thence they forced an entrance into the capillaries in such numbers as to stop the circulation, or at least to offer a very great impediment to it.

Here, we claim, they change their form and get a tail and then pass out into the general circulation. We see in their presence in the liver a ready explanation of the icterus which occurs in pernicious anæmia. As far as the investigator's researches have yet gone they have led him to the belief that the origin of these organisms is to be found in a fungus growing in carious teeth. All the patients whom he examined had dental caries and a fetid breath. Hence he concluded that the frequency of pernicious anæmia in pregnant women was to be explained by the fact that women in this condition often had bad teeth. And further, since almost the entire population of Zurich is afflicted with unsound teeth, an explanation of the unparalleled frequency of the disease under question in that city is afforded. The dependence of fatty heart upon the same conditions appears to Professor Frankenhäuser, to be not only possible, but even probable. If this most promising field of investigation be cultivated with sufficient energy and imagination, it may yet come to pass that the dentist, with his ounce of prevention, will take rank as the greatest benefactor of the human race.

News of the Week.

TESTIMONIAL TO MR. ERNEST HART.—A testimonial to Mr. Hart, editor of the *British Medical Journal*, was recently presented to Mrs. Hart at the Grosvenor House by express permission of the Duke of Westminster. The testimonial was a portrait of himself, and was presented to him by Mr. Spencer Wells, President of the Royal College of Surgeons, and treasurer of the fund. The testimonial was a fitting and deserved recognition of the invaluable service rendered to the medical profession of England by Mr. Hart.

A FORTUNATE HOSPITAL.—St. George's Hospital, London, is shortly to come into a legacy of \$100,000.

THE AMERICAN PSYCHOLOGICAL JOURNAL.—This is a new quarterly journal issued by the National Association for the Protection of the Insane and the Prevention of Insanity. It is edited by Dr. Joseph Parrish, with A. A. Chevallier, and Drs. W. W. Godding, C. L. Dana, H. H. Bannister, and J. C. Shaw, associates. The publishers are P. Blakiston, Son & Co., Philadelphia. The first number is certainly a most promising one, containing original articles from such well-known names as J. Milner Fothergill, Norman Kerr, William Julius Mickle, W. W. Godding, C. K. Miles, Walter Channing, Crothers, H. Marion Sims, and others. The publishers have done their work excellently.

THE JOURNAL OF COMPARATIVE MEDICINE AND SURGERY.—This journal has appeared enlarged and under charge of a new publisher. It has established itself as the leading journal in America, on matters of comparative pathology and physiology, as well as in veterinary medicine. It contains a great deal of practical interest to all medical men.

THE NEW YORK NEUROLOGICAL INFIRMARY.—An institution bearing this title, and having for its object "the gratuitous treatment of the poor for all diseases of the nervous system," has been incorporated in this city. Dr. J. L. Corning, Dr. M. Josiah Roberts, and Messrs. Sidney Green, John T. Sherman, and Benjamin Crane have been elected trustees for the first year.

THE INDIANA STATE MEDICAL SOCIETY meets in Indianapolis, on May 8, 1883.

A RECIPROCITY-ANNUITY-BOND ASSOCIATION has been organized in Chicago, with branch offices in St. Louis, Detroit, and Pittsburg. The *Indiana Medical Journal* commends it, and says it is organized by and for physicians. It pays annuities for ten years or more. We should advise our readers to examine the institution very carefully before putting money in it.

SIR ERASMUS WILSON appears to have gone daft in his last effort of philanthropy. He wishes to raise funds for the erection of a statue to John Brown, late first waiter to Queen Victoria.

AN ELECTRIC HEAD-LIGHT.—M. M. Paul Hélot, surgeon to the Rouen Hospital, and Q. Trouvé, have devised an electric lamp to be worn on the forehead, in the examination of cavities. The light is very intense, and will last for hours.

A REGULAR PHYSICIAN.—The following, says the *Indiana Medical Journal*, are the favorite prescriptions of a so called regular physician of Indianapolis, and a member of the County Medical Society, who practises his trade, we will not say profession, in the northeast part of this city:

R. "Lung Remedy," which properly translated means "Mrs. Rhorer's Lung Remedy."

R. "Simmon's Liver Regulator."

R. "My Pills."

R. "My Tonic."

THE MARYLAND MEDICAL JOURNAL will be published weekly, commencing May 3d. We congratulate our contemporary upon this evidence of its well-deserved success.

THE PRESBYTERIAN EYE, EAR, AND THROAT CHARITY HOSPITAL, of Baltimore, whose new building was recently dedicated, is supported in a somewhat novel way. Each of the Presbyterian Churches in the city in succession takes charge of the hospital for a month, paying all expenses. When a congregation is too small to bear the expense, two are united.

The hospital has accommodations for twenty in-patients.

BILL TO REGULATE THE DISTRIBUTION OF BODIES AMONG MEDICAL COLLEGES.—A bill to regulate the distribution of bodies from public hospitals, prisons, morgues, etc., among medical colleges has passed the State Senate.

THE WEST VIRGINIA MEDICAL SOCIETY will hold its annual session at Grafton, May 16, 1883.

THE AMERICAN MEDICAL ASSOCIATION meets at Cleveland, O., June 5th, 6th, 7th, and 8th.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION holds its fifth annual meeting in this city, at the Academy of Medicine, May 21st, 22d, and 23d. The sessions begin at ten o'clock A.M.

A CASE OF ADIPOCERE.—The *Cincinnati Medical News* vouches for the following: "There is on exhibition in Cincinnati, at the present writing, the body of a woman who died in 1859, near Dupont, Indiana; and, after remaining in the grave until last November, for a period of *twenty-three years*, her grave was opened, that her remains might be reinterred in the Wesleyan Cemetery, near Cincinnati. She was the mother of a Mr. Robert Leitch, of the printing works, 12 West Eighth Street, Cincinnati. When the coffin was reached, in the process of disinterring, although made of common poplar, not a durable wood, it was found in almost perfect condition, the wood seeming to be firm and solid. When lifted from the grave the immense weight was remarked. On reaching the depot in this city, it required six men to lift it from the car to a wagon. A glimpse at the interior showed the cause of the great weight. The body was found to present a normal form and shape; and, although black, the outline was almost perfect. There was the head, with its sunken eyes, withered nose and chin, hair along the edge of the forehead; the body flattened, and somewhat spreading; the upper part of

arms lying alongside of the body, and the lower portion of them with the hands placed across the body. The arms and hands, as they lie across the body, indent it. Only the bones of the fingers are remaining. The abdomen is considerably flattened, the sides bulging considerably. The mammary glands of the breast are easily outlined. The thighs and legs preserve their contour, but seem enlarged. The blackened appearance is caused by the burial garments adhering closely to it, their fibres being easily distinguished. The present weight of the body, we understand, is about five hundred pounds. The deceased, when living, weighed about two hundred, and was seventy-three years old.

QUARANTINE.—On account of the reported existence of yellow fever in Cuba and other southern islands, the National Board of Health has decided to establish quarantine stations on the Southern coast earlier than usual this year.

A MOVEMENT AGAINST COUNTER-PRESCRIBING.—A daily paper is authority for stating that a movement has been set on foot in this city by medical men, which has in view the prevention of apothecaries and drug clerks from prescribing for patients and from copying the prescriptions of physicians—a practice which has become very common in some quarters of the city. It is proposed, as the most feasible mode of giving authority to the protest and declarations of the profession, that action shall be taken by the County Medical Society, and that the registered members of that body shall pledge themselves to withdraw their patronage, and to use their influence to induce patients whom they attend to withhold their prescriptions from stores whose proprietors are known to be in the habit of recommending patent medicines or of compounding potions without medical authority. According to numerous observers, while most of the larger and more important drug stores in the city refrain from all such practices, others are managed by men who style themselves physicians or doctors, and spare no pains to obtain patients, even going so far as to make criticisms on prescriptions sent to them by regular practitioners, with a view to impair confidence in them and to divert the fee for prescribing into their own pockets.

A BOSTON ENTERPRISE.—We have received a circular which states that "To show the value of nutrition in developing life the — — Food Co. have established a free hospital of seventy beds." Forty beds for diseased and orphan infants; thirty beds for women with chronic disease.

THE JACKSONIAN PRIZE OF THE ROYAL COLLEGE OF SURGEONS has been awarded to Mr. Anthony A. Bowlby, F.R.C.S., for an "Essay on Wounds and other Injuries of Nerves, their Symptoms, Pathology, and Treatment."

COMPELLED TO RESIGN.—It is reported that Dr. Joseph W. Howe, late Professor of Clinical Surgery at Bellevue College, has been compelled to resign that position in consequence of the stand he has taken in favor of the new Code of Ethics. It is said that several other gentlemen connected with this college have recently been obliged to change their views or keep silent regarding them.

THE BALTIMORE MEDICAL COLLEGE, which was started two years ago on a "Christian" and co-educational basis, has, says the *Maryland Medical Journal*, abandoned both these features, "Not that it loves Cæsar less," but it prefers substantial success to the propagation of ideals.

THE MICHIGAN STATE MEDICAL SOCIETY holds its annual meeting at Kalamazoo, May 8th, 9th, and 10th.

KENTUCKY STATE PHARMACEUTICAL ASSOCIATION.—The regular annual meeting of the Kentucky Pharmaceutical Association will take place at Lexington, Ky., Tuesday, May 22d, at 3 P.M. As the new pharmaceutical law comes up for discussion, a large attendance is requested, and all members are urged to bring as many new members as possible.

DR. LYON PLAYFAIR has received the Knight Commandership of the Order of the Bath.

THE BRAZILIAN GOVERNMENT has awarded a gratuity of \$1,750 to Dr. John Baptist Lacerda for his discovery of the antidotal virtues of permanganate of potash in relation to snake-poisoning.

PROFESSOR T. H. HUXLEY and Mr. J. Tomes have been elected Honorary Fellows of the Royal College of Surgeons.

STATE IDIOT ASYLUM AT SYRACUSE.—Dr. Henry B. Wilbur, Superintendent, since the foundation of this institution, died suddenly, May 1st. He was a pioneer in the education of idiots in this country.

DR. RICHARD JOSEPH, formerly of Marblehead, Mass., disbursing officer of the Department of the Interior, died of heart disease, May 1st.

COLLEGE COMMENCEMENT—MORE DOCTORS.—The first Annual Commencement of the Woman's Medical College of Baltimore was held May 1st. One graduate, a former pupil at the Woman's Medical College in New York, received a diploma. A nucleus of this kind frequently yields many fold.

DR. ORTON, of Milwaukee, accused of producing an abortion upon his intended bride, was, on April 28th, discharged by the Judge of the Criminal Court.

FLORIDA AS A HEALTH-RESORT.—The *Atlanta Post-Appeal*, speaking of the recuperative powers of Florida, says that when the invalid's first week's hotel bill is presented he usually says, "I guess I'm well enough to start for home this afternoon."

THE PHARMACEUTICAL EXAMINATIONS.—The following were the successful candidates at the pharmaceutical examinations held in Montreal, April 27th: *Major Students*.—Charles E. Scarff, Alpheus Davidson, E. Leonard, Alex. Robert, Ernest G. Swift, A. Dugal. *Minor*.—A. E. Holden, L. Flannigan, Joseph H. Noad, R. A. Kerry, A. R. Read, F. Baker, J. L. Beaudry, W. Punchard, M. B. Rice, and F. G. Daniel.

THE ARGENTEULI PRIZES.—The highest of these (\$1,200) has been awarded to Dr. H. J. Bigelow, of Boston.

THE NEW SMALL-POX HOSPITAL.—The Board of Health has advertised for bids preparatory to a contract for the building of a boiler-house adjacent to the new

small-pox hospital at North Brothers Island. Connected with the boiler-house, which is to furnish steam for warming the main building, will be a laundry, a kitchen, and sleeping rooms for the "help." The hospital has four wards, each having ample space for sixteen beds, though, in cases of emergency, a third row of eight beds can be added without any serious overcrowding. It is proposed soon to erect an administration building, where the doctors, matron, and trained nurses will live, and also another pavilion as soon as needed. The hospital cannot be occupied until the heating apparatus is complete, and the island is supplied with Croton water, which is about to be done by the Department of Public Works. With a view to beautifying the surroundings, as well as to afford future protection to the buildings from the high winds that occasionally sweep over the island, one hundred young elms have been planted there, to which additions will be made at a future time. It is intended to make this spot as attractive as possible to those unfortunate ones, who, by reason of a loathsome disease, are involuntary exiles from their friends and homes.

A BAD LUNACY BILL.—Mr. Austin Abbott calls attention in the *Times* to the very bad features of Assembly Bill No. 636, for amending the lunacy laws,—a bill which has a strong backing. If this bill becomes a law, we are told that one can be taken and confined in an asylum upon a certificate made by two qualified physicians (made without consultation between them), and indorsed by the approval of only a Justice of the Peace within the county, in which the alleged insane person resides, without judicial examination on his part other than of the contents of the certificate. He "may" take evidence, but is not required to. Upon such a certificate a person so confined may, without further authority, and at any time within thirty days, be removed from one asylum, public or private, or home, or retreat to another, and with no restriction against removal beyond the State. It is easy to imagine the task which the friends or counsel of a person thus committed in *ex-parte* proceedings would have in endeavoring to trace him from asylum to asylum, for there is no provision for any public record of the proceedings.

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, of which there is a medical section, meets this year at Rouen, August 16th to 23d.

A MEDICAL FRAUD EXPOSED.—The *Therapeutic Gazette* has with great completeness exposed the fraudulent character of "a retired missionary, returned from South America, whose sands of life had nearly run out;" but who had sufficient vitality to put on the market a precious specific for erring but noble young men. It cost, says the *Gazette*, about two cents a box, and it was selling for \$3.50.

HOMO NEVADENSIS.—California scientists are serious, says *The Times*, in their speculations concerning the so-called fossil human footprints found in the sandstone of Nevada, near the State prison quarry. Dr. Harkness, the explorer in these footprints, is confident that he has discovered a new species of the *genus homo*, and he sub-

mits the following description of his scientific find: "Homo Nevadensis (Harkness): Length of track, 18½ inches; width at ball of foot, 8 inches; width of heel, 6 inches; average length of step, 27 inches; length of stride, 54 inches; width of trackway, 18 inches; angle with the median line, about fifteen degrees. Each track is modified in form by a sandal or other protection to the foot." It has been suggested by rival persons that the prehistoric and giant man was only an early emigrant to California from St. Louis or Chicago, a foot 18½ inches long being no novelty in either of those cities, according to their own newspapers.

DR. GEORGE B. HAWLEY, seventy-two years of age, for many years a prominent physician of Hartford, Conn., died April 19th.

INSPECTION OF THE THROAT WITHOUT INSTRUMENTS.—Dr. Samuel W. Francis, of Newport, R. I., writes that very often it is difficult to depress the tongue of a patient who is suffering from sore throat, diphtheria, follicular tonsillitis, or other affections of the fauces, etc., and suggests that they be told to open their mouth, in front of a good light, and simply, but with force, say: *Arh! Barrh!! Varrst!!!* LIFE—enunciating each word some few seconds. Dr. Francis has tried this, and not only obtained an excellent view, but the different positions of the uvula and surrounding parts, greatly assisting the diagnosis and treatment of the disease.

M.D. OR M.B., IN GREAT BRITAIN.—Dr. Parks, of Ashton, R. I., in an interesting letter commenting on "Our London Letter," says that the correspondent is wrong in some particulars as to the mode in which English practitioners are designated. For instance, he says "only university graduates *can* call themselves Dr. (M.D. or M.B.)." This is true as regards M.D. He being a *Doctor* of Medicine can call himself Doctor, while the M.B. being only a *Bachelor* not a Doctor, *can*, in common with all other gentlemen, only call himself Mr. He also states that physicians are not *nearly* all graduates, and do not style themselves Dr.; the vast majority of them being licentiates of one or other of the Colleges of Physicians of London, Dublin, or Edinburgh, and as such are only *entitled* to the designation of plain Mr.

THE NASHVILLE MEDICAL SOCIETY.—Dr. J. L. Watkins writes that the "parturient stress" is over, and that this Society is the outgrowth of the late meeting of the State Medical Society. Its officers are Dr. N. D. Richardson, *President*; Dr. W. J. McMurray, *Vice-President*; Dr. J. L. Watkins, *Secretary and Treasurer*. The Society will meet twice a month, and has every hope and evidence of success.

ARMY SANITATION IN INDIA.—Dr. Cunningham, in his report concerning the health of the European army in 1881, says that, although the rate of sickness was high, the ratio of mortality was less than in former years. This result he attributes to improved sanitation and greater attention to the health of the soldiers. The largest number of deaths occurred from enteric fever; cholera ranks second. In Bengal the rate of mortality from enteric fever was 2.62; Bombay, 2.83; and Madras, 0.58 per thousand.

THE BACILLUS OF TUBERCULOSIS.—In the *Centralblatt für Klinische Medizin*, April 14, 1883, Finckler and Eichler express the opinion that other bacilli than the tubercular, stain blue, and do not yield the color to nitric-acid washing; that the bacilli of tubercle offer greater resistance to the reagents than do other micro-organisms; that nitric acid may so completely remove the color that pure water will not restore it, however prolonged the bathing; and finally, that the claim that Bismark brown does not affect them is not strictly accurate.

CHLOROFORM IN MIDWIFERY.—Dr. Fancourt Barnes, in the *British Medical Journal*, expresses the opinion that the reason why chloroform is so well borne in midwifery lies in the condition of the heart during pregnancy, namely, that of hypertrophy, developed during gestation.

ABSENCE OF THE CHARACTERISTIC ERUPTION IN TYPHOID FEVER.—Dr. Whipple, of London, related at a late meeting of the Clinical Society two cases of typhoid fever in which there was found, at autopsy, the characteristic intestinal lesion, but the typhoid eruption was not found; on the other hand, an eruption was present which resembled that of scarlet fever. He does not object to the view that scarlet fever and typhoid fever are frequently concurrent.

CORROSIVE SUBLIMATE AS AN ANTISEPTIC IN MIDWIFERY.—Dr. Tarnier recommends that the genital region be washed and injected with corrosive sublimate (1 to 2,000) and that the mattresses and napkins be disinfected by the same fluid, during the process of labor.

THE INDEPENDENT PRACTITIONER.—Dr. Leigh H. Hunt has resigned the editorship of this journal.

ROYAL COLLEGE OF SURGEONS.—At the recent pass examination for the diploma of membership, the candidates were given two hours in which to answer three out of four questions in midwifery and diseases of women. One of the questions was as follows, and evidently it was sufficiently broad to occupy one-fourth of the time allotted: "In what circumstances is the operation of craniotomy indicated, and how would you complete the delivery when the head has been perforated?"

Reviews and Notices.

LECTURES ON ORTHOPEDIC SURGERY AND DISEASES OF THE JOINTS. By LEWIS A. SAYRE, M.D. Second Edition, pp. 569, with 324 illustrations. New York: D. Appleton & Company.

THE first edition of this work has been before the profession since 1876, and has been considered, as it purported to be, a record of the views and procedures advocated by its author, rather than a critical review and résumé of all the principles and practices comprised in orthopedic science. The edition just issued possesses the same general features and has been enlarged and more fully illustrated, so that it may be considered a compendium of the present views and methods advocated by the distinguished author. A large number of illustrative cases are cited, some of the chapters are rewritten and brought up to the present time, and fifty-two new engravings have been added, so that the work may be considered as complete. The chapters upon Spondylitis and Lateral Curvature will be particularly welcome to the profession at the present time, as they em-

body the views of the author upon the use of the Plaster Jacket in these affections, and contain many valuable suggestions regarding its application and practical uses, together with a defence of its employment as a method of treatment. The objections to the jacket are fully considered and refuted, and the indications for its employment are laid down with the exactness of experience.

The book contains thirty-two chapters, of which five are devoted to the consideration of diseases of the hip-joints, and a table of seventy-two cases of exsections of the head of the femur, performed by the author, is added, the table having been compiled by his son, Dr. L. H. Sayre—the latest operation recorded having taken place in December, 1882.

Of Hutchinson's method for the hip, he states, "I am therefore reluctantly compelled to abandon this plan of treatment, although, when first proposed, I gave it a most cordial endorsement before I had any practical experience with it," and cites a case to illustrate the principles involved.

An illustrated frontispiece, drawn by Dr. Heitzman, and illustrating a section through an exsected hip joint during the process of reproduction, is not the least of the attractive features of the book.

Taken as a whole, the book will prove a valuable addition to the library of the general practitioner, as well as the orthopedist, both as a work of reference and as a guide to the principles and practice pertaining to this much-neglected branch of surgery, and it should meet with the general commendation it deserves.

A SYSTEM OF HUMAN ANATOMY, INCLUDING ITS MEDICAL AND SURGICAL RELATIONS. By HARRISON ALLEN, M.D., Professor of Physiology in the University of Pennsylvania. Section IV., Arteries, Veins, and Lymphatics. 4to, pp. 458. Philadelphia: H. C. Lea's Son & Co. 1883.

SECTION IV. of this admirable work, treating as it does of the vessels of the body, is of peculiar interest to the practitioner. The author goes over the whole ground with his usual thoroughness, discussing the various regions not only from an anatomical, but from a clinical, point of view. This latter element of the work gives it a unique and peculiar value, as the subjects discussed are made of equal interest to the surgeon and physician. The descriptive text is terse and accurate, omitting no detail and giving due prominence to important facts, and due consideration for leading principles. The illustrations, which show a great improvement over those in the previous sections, are not as numerous as they might be. Still the excellent descriptions in the text more than make up for the deficiency. The illustrations of the venous circulation are particularly good, and are well colored.

THE MEDICAL AND SURGICAL HISTORY OF THE WAR OF THE REBELLION, Part iii., Vol. ii., Surgical History. Prepared under the direction of JOSEPH K. BARNES, Surgeon-General United States Army, and D. L. HUNTINGTON, Surgeon United States Army. First issue. 4to, pp. 986. Washington: Government Printing Office, 1883.

THE present volume completes the surgical series of the Medical and Surgical History of the War of the Rebellion. Continuing the general scheme of series, the treatment of regional injuries of gunshot origin is continued, leading off with those of the lower extremities. The succeeding chapter gives an interesting account of miscellaneous gunshot injuries, then follow facts general and statistical relative to the nature, peculiarities, and effects of the missiles and projectiles, and the graver attending complications. Under the latter heading are considered secondary hemorrhage, erysipelas, pyæmia, gangrene, and tetanus. The chapter on Anæsthetics in military practice is an exceedingly interesting and instructive one, embodying as it does a wide experience,

under all possible conditions, of surgical operations. The historical sketch of the medical staff, and a description of the *materia chirurgica*, give a very fair statement of the great resources on the field and in hospital which were so efficiently utilized during the late war. The methods of field, railway, and water transportation of the wounded are given in necessary detail, and serve to prove what can be done in promptly caring for the wounded, even on the largest possible scale and in the face of what might generally be considered as insurmountable obstacles. The particular value of this noble volume to the general surgeon centres more particularly in those portions which treat of the result of gunshot fractures in the lower extremities. Under the respective headings of injuries to hip, thigh, knee, leg, and foot, are grouped a mass of facts concerning the characters of fractures in these localities, their methods of treatment and results, the accuracy and value of which cannot be overestimated. The painstaking accuracy with which the various facts of history are summarized, and the deductions which are drawn therefrom, reflect the highest credit upon the accomplished author of the present volume. Here come in also the discussion of amputations in all situations and under all conditions, giving the results in a mass of statistics, the value and accuracy of which have never before been equalled. The careful study of these statistics will serve to settle many facts heretofore in doubt, and will mark the value of new lines of practice which must always redound to the credit of American surgery. It would be useless to attempt to formulate the conclusions arrived at. Such would be impossible short of noticing each chapter by itself as an independent volume, for such each chapter could be consistently considered. The illustrations, photo- and chromo-lithographic, are fully up to the previous standards, which is saying everything for them. The wood-cuts are also admirably executed. Dr. D. L. Huntington, who has prepared the present volume, has satisfactorily discharged the great responsibility imposed upon him, and has in every way shown himself the worthy successor to the late lamented surgeon, George A. Otis, whose name is also justly and appropriately placed upon the title-page of this monumental volume.

LABOR AMONG PRIMITIVE PEOPLES. Showing the Development of the Obstetric Science of To-day from the Natural and Instinctive Customs of all Races, Civilized and Savage, Past and Present. By GEORGE J. ENGELMANN, A.M., M.D., Professor of Obstetrics, Post-Graduate School of Missouri Medical College, St. Louis. 8vo, pp. 227. St. Louis: J. H. Chambers & Co. 1883.

THE second edition of this work comes to us revised, enlarged, and rearranged. As we have already said, it is one of the most interesting and instructive volumes that can be placed in the hands of student or practitioner. It represents an immense amount of research, which is utilized in the direction of making this one of the most practical obstetrical guides ever presented to the profession. It contains a large number of illustrations, representing the natural and instructive customs of the primitive races during the parturient act. The medical man who studies nature as he finds her will gain many a useful hint by the perusal of Dr. Engelmann's entertaining history.

HAND-BOOK OF VERTEBRATE DISSECTION. By H. NEWELL MARTIN, D. Sc., M.D., and WILLIAM A. MOALL, M.D. Part II. How to DISSECT A BIRD. Pp. 174. New York: Macmillan & Co. 1883.

IN reviewing Part I. of this series we commented upon the object aimed at in them. The present volume is equally good with the first, and was, perhaps, still more needed. The directions are carefully given, and the illustrations, though not numerous, are sufficient.

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 6, 1883.

JAMES B. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

DR. BEVERLY ROBINSON presented to the Society a case of

LARYNGEAL PARALYSIS, ILLUSTRATING ALSO SYPHILIZATION BY BÖCK'S METHOD.

The patient was a German, aged forty-two, and had lived in Copenhagen. Twenty-five years before he had contracted a chancre, which appeared about ten days after coition. About three weeks later, an eruption on the body appeared. He went to Professor Böck's hospital, and was put under treatment. He was first inoculated in three places on the chest with syphilitic virus; six days later the vaccination was repeated; it was then repeated every third day, three vaccinations each time. They were made upon the chest, arms, and legs. Gradually the inoculation effects became weaker, and finally the virus produced nothing but a superficial scab. The whole process lasted about three and one-half months. During that time he was obliged to lie flat on his back; he suffered intensely and would not, he said, "go through it again for a million dollars."

Since that time, however, he had been perfectly well, and had never noticed any symptoms of having syphilis, although he had taken no medicine. He had married, and his wife had had several healthy children and no miscarriages.

As regards the throat trouble, examination showed that the fauces are intensely congested and marked by a large number of varicose veins. The uvula large, infiltrated, and evidently quite relaxed. The epiglottis was red; the posterior third of the true vocal cords had a pink coloration.

In phonation, the free margin of the left vocal cord presented a half oval excavation very appreciable to the eye, as reflected in the small laryngeal mirror. This excavation was probably due to paralysis of the tensor muscles on the same side of the larynx.

The interesting feature, said Dr. Robinson, in the case, to be determined, beyond the fact of the patient being a notable example of Professor Böck's plan of treatment, is whether or no the intra-laryngeal paralysis be proof of a syphilitic deposit, possibly of gummatous nature, in the intrinsic muscles of the vocal organ.

In view of the limited localization of the paralysis, of the man's general excellent physical condition, and of his inability to recognize elsewhere any pathological lesion capable of explaining the localized laryngeal paralysis, the speaker was of the opinion that this must be received as the most *probable* explanation, and, notwithstanding the fact that the patient had only had few and very mild symptoms at any time, of constitutional syphilis.

DR. SAMUEL SEXTON read a paper, entitled:

EARACHE IN CHILDREN.

[The paper is published in full on page 480.]

The paper being open for discussion, DR. R. F. WEIR, referring to the question of paracentesis for the relief of pain in acute otitis media, said that, in his experience, the external canal often became swollen and paracentesis was a difficult and painful process. It was better, as a rule, especially in children, to let the drum alone. In adult subjects he performed the operation oftener. For the pain he used morphine and atropine, with injection of hot water, pouring the water into the ear—not syringing it. He had abandoned the use of leeches, for the reasons given by Dr. Sexton.

DR. BEVERLY ROBINSON had seen relief from the application of leeches in children, when nothing else did any good. He had also seen a great deal of relief from the application of the continuous douche. In some instances he had seen salicylate of soda in large doses relieve aural pain.

DR. KINNICUTT said that his experience was confirmatory of Dr. Weir's. In the earache of children the simple pouring of hot water into the ear would often suffice, the child falling asleep during the process.

DR. ABBE frequently used the old-fashioned remedy of laudanum on cotton, and it was generally satisfactory. If necessary, he gave an anodyne internally.

DR. SEXTON said that he very seldom had to use anodynes to children, but often gave them to adults to bridge over the night. He thought that large doses of narcotics tend to make the trouble worse sooner or later. Warm water was often beneficial, but if poured directly down upon the drum-head it might do harm, and hot air (from hot salt or sand-bags) would accomplish just as much.

DR. NICOLL had obtained very satisfactory results from the use of hot water in the shape of the douche.

DR. WALKER spoke of the relief sometimes obtained with adults by shutting the mouth, holding the nose, and making a forcible expiration so as to drive the air into the middle ear. Good effects were observed also by the reverse method, making an inspiratory movement so as to suck the air from the tubes.

DR. SEXTON said that this latter process had often to be done methodically by adults in order to clear up the ear. It was often supplemented by swallowing at the end of the inspiration.

DR. A. A. SMITH had been in the habit of using warm douches, and the application of heat in the form of hot salt bags. He frequently found it necessary to give in addition a full anodyne. In one case he had blown chloroform vapor into the ear with good result.

A discussion was opened by the Society upon the paper read by Dr. Beverly Robinson, entitled

NOTE ON RAPID OR SUDDEN HEART-FAILURE IN ACUTE INFECTIOUS DISEASE, NOTABLY IN DIPHTHERIA AND TYPHOID FEVER.

[The paper is published in full on page 484.]

DR. H. F. WALKER had had cases similar to those described by Dr. Robinson, especially cases of diphtheria. His patients, however, had never been completely out of danger. In a case of diphtheria, the patient had reached the ninth day; he was doing well in the morning, at night he was dead. In another case death was still more sudden. There seemed to be heart paralysis, but no post-mortem was made.

DR. F. P. KINNICUTT, said that in the various acute infectious diseases, in diseases accompanied by high temperature, as well as in pericarditis and endocarditis, pathological research has demonstrated the very frequent existence of a parenchymatous myocarditis. The inflammatory process may be diffused or circumscribed; the cardiac muscle becomes swollen and pale in color; numerous minute granules, partly soluble in acetic acid, make their appearance in the muscular fibre, the transverse striæ become indistinct and finally disappear. This process may proceed to a condition of true fatty degeneration.

In typhoid fever we have clinical evidence of the existence of degeneration of the heart-muscle, in the impairment or absence of the impulse and of the first sound of the heart; and in individuals dying of the disease a degeneration of the kind which I have described is found to be the rule. Have we not in this fact a rational explanation of both the gradual heart-failure which obtains so frequently in this disease and of the sudden or acute cardiac paralysis?

The inflammatory affection of the muscular fibre is necessarily attended with more or less dilatation of the

heart; a sudden movement or unusual exertion may well be sufficient to produce a correspondingly rapid *increased* dilatation with fatal syncope. In diphtheria, a fatal heart-paralysis, it seems to me, may be ascribed, in a certain number of cases, to a like pathological process; in others, to a paralysis referable to a lesion of the nervous system. To the latter class are especially to be referred those cases of sudden death occurring during apparent convalescence from the disease.

DR. C. L. DANA said that the French observers had recognized the fact that in acute infectious disease the poison sometimes especially attacks the heart. In the descriptions of typhoid fever a "cardiac form" had been described.

Sudden deaths from heart-failure, in persons apparently doing well, occur also in other diseases, as in acute nephritis and in pneumonia. The speaker had seen instances of this kind.

DR. ROBINSON said that in typhoid fever we find granular and fatty degeneration of the heart, but he had not observed that this degeneration was any more marked in persons who had all along had symptoms of cardiac weakness than in others who did not die directly from heart-failure.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 28, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR

(Continued from p. 443.)

DR. G. L. PEAODY presented on behalf of a candidate a specimen of *fibroma* of the *sciatic nerve*.

He also presented specimens illustrating

THE LESIONS IN SYPHILIS OF THE BRAIN, LUNGS, AND KIDNEYS.

"The patient, an Englishman, fifty-five years of age, first consulted me in January of last year. He was a drinker of beer and a smoker, whose general health had always been good. Three years previously he had had a chancre followed by a rash upon the body, soreness of the throat, falling out of hair, pain in the crests of the tibiae and other manifestations of syphilis. At the time of his infection, and subsequently up to the present, he says he has had no treatment for his malady, nor has he felt much need of relief. Ten days before consulting me he had a sudden sharp pain in the head posteriorly on the right side. It soon left this side and went to the left occipital region when it persisted obstinately. This was also accompanied by a severe sore throat. The pain in the head was much aggravated by the recumbent position and deprived him of sleep, except such as he could enjoy in the sitting posture. At this time there was also marked loss of power on the right side, notably in the right hand, but also, though to a less extent, in the right leg and thigh. He complained also of a sensation of formication in both extremities on this side. I examined the fundus of his eyes at this time with the ophthalmoscope and found it normal on each side. The tendon reflex was normal on both sides.

"Under the use of iodide of potassium in increasing doses—a drachm and a half three times a day having been finally reached—all these distressing symptoms gradually passed away and he was able to resume his work. I cautioned him at this time never to neglect the warning which a recurrence of any of these manifestations ought to convey to him. Late in May he again presented himself for treatment in precisely the same condition in which he had been when he first came under observation, except that the pain in the left occipital region was more severe than before. My warning had not been regarded, and his pain had returned two weeks before his coming this time to me.

"Iodide of potassium was again faithfully tried, but

without avail, even in the same large doses as before. After some days he was given mercury in combination with it, and then he began again slowly to improve. Convalescence this time was much more tardy than before, and, in fact, it was nearly two months from the beginning of the second attack until he was entirely free from pain. He did recover, however, completely, so far as his subjective symptoms are concerned. His wife tells me, however, that he became morose and sullen and continued so as long as he lived.

"I again warned him as before, not to allow any such symptoms, should they recur, to go a day untreated; and he promised, as before, that my warning should not be disregarded.

"About the end of August he was again attacked in a similar way, and he again neglected to apply for relief until his symptoms had existed two weeks. This time they seemed more severe than ever before, though the pain, however, was on the right side. It was described by him as a sharp pain, very severe, diffused over the posterior part of the right side of the head. forcible palpation and gentle percussion over the head in this situation gave him much pain. He was at this time distinctly, though to a slight extent, hemiparetic on the left side.

"The glands in his groins were slightly enlarged and the crests of the tibiae were slightly roughened. This time, in my absence from town, he was treated by a colleague by iodide of potassium, but in smaller doses than those to which he had been accustomed. The largest amount given in any one day was a hundred and twenty grains divided into three doses. Opium, morphine, and bromide of potassium were also administered at times to relieve his pain, which was even more severe than usual.

"Having been very apathetic at first, he soon became dull and stupid. In a few days stupor deepened into coma; he became unable to take his medicine; coarse râles were heard over his chest; he coughed a little in his comatose condition and his temperature began slowly to rise. His pulse and respiration soon became rapid; and, nine days after he had come under observation, he died with a temperature of 107°, having been comatose during the last three days of his life.

"I made the autopsy twenty hours after death. The calvaria was observed to be unusually thin. The convolutions presented the usual appearances of senile atrophy, the fissures beneath them being deeper and wider than in middle life, and there being a large amount of serum in the meshes of the pia mater in these situations. The arteries at the base showed a few small patches of atheroma. In the fissure of Sylvius on the right side was a thin yellowish mass surrounding the middle cerebral artery, extending about one-third of an inch along the vessel. The thickness of this mass was nowhere as great as the diameter of the vessel itself, but it was quite evident that the calibre of the vessel had been reduced by the pressure thus exerted. The corpus striatum on this side was distinctly softened, and in this situation the roof of the ventricle was loosely adherent to its floor.

"The microscopic examination of sections made through the middle cerebral artery and the surrounding mass is of considerable interest. The yellowish mass is found to be partly in the adventitia of the vessel and partly external to it. In the adventitia it presents the appearance of a densely aggregated mass of small round cells with a small amount of fine fibrous stroma between them. External to this the material presents a granular and amorphous appearance.

"Within the vessels in these sections is also seen a new growth—a somewhat crescentic-shaped growth—of connective tissue from the intima. This is a good illustration of the form of endarteritis obliterans, which was formerly ascribed only to syphilis. It is now known to occur under various other conditions. I have myself found it in the cerebral arteries in subjects in whom there was no reason to suspect syphilis, as well as in syphilitics, though less frequently. I have also found it in the arte-

ries of the kidneys in chronic diffuse nephritis, and in the lungs in chronic phthisis when no indication of syphilis existed. Recently I have found the same form of endarteritis in two malignant tumors, both epitheliomata, the one of the tongue and the other of the antrum. The lungs of this subject presented several small syphilitic growths surrounded by areas of catarrhal pneumonia. The right kidney contained on its surface a similar growth. Both kidneys showed the lesions of diffuse nephritis, not far advanced.

"I place under the microscope sections of the middle cerebral artery surrounded by the gummy growth, and showing in its interior the lesion of endarteritis obliterans in two places; also a section through one of these growths in the lungs, together with the zone of pneumonia surrounding it.

"The special interest in this case is in the coincidence of these two cerebral lesions at the same point in the course of an important artery. I do not think that either one alone would have interfered with the blood-supply sufficiently to produce cerebral softening and death, but together their influence could not be long withstood."

DR. VAN SANTVOORD presented

A UTERUS UNICORNIS

removed from the body of an infant seven months old. The organ was conical in shape, and on the left side the Fallopian tube and the ovary presented a normal appearance. On the right side the ovary was located in the right iliac fossa, and the Fallopian tube was correspondingly displaced outward, and terminated in a club-shaped, fleshy mass, one-fourth of an inch in thickness at its extremity, which extended toward the uterus and gradually lost itself in the broad ligament just at the upper end of the cervix. There was no opening in the uterus corresponding to the Fallopian tube on the right side, although the tube itself was pervious. The club-shaped muscular mass represented the right horn of the uterus. There was no septum in either the cervix or the vagina.

SUBPERIOSTEAL HÆMATOMA.

DR. VAN SANTVOORD also presented a dried specimen illustrating subperiosteal hæmatoma occurring on the skull of an infant, a foundling in the Randall's Island Hospital. There was no history. Over the right parietal bone an elastic fluctuating tumor was found, when the child was first seen, with its edges hard and elevated, and what felt like a depression beyond the borders of the tumor. The child died of marasmus when twenty-two days old.

DR. HEINEMAN presented a specimen illustrating

CEREBRAL HEMORRHAGE, OSTEO-FIBROMA OF UTERUS, AND PYELO-NEPHRITIS.

"The patient, aged sixty, was admitted to Mount Sinai Hospital March 16, 1883, in a semi-conscious condition. At eight o'clock in the morning she was found on the floor of her room with the right side of her body paralyzed. She was apparently conscious when found, though unable to speak.

"On admission patient is inclined to sleep. She can be roused, but is dazed and yawns. There is slight difficulty in deglutition; cannot speak, but answers intelligently by a nod of the head after being thoroughly roused. Has right hemiplegia. Slight systolic aortic murmur. Arteries slightly thickened. On the succeeding day her temperature rose to 101° F. There was marked anæsthesia of right upper extremity; fingers were flexed; there was slight anæsthesia of the right lower extremity. There was retention with overflow of urine.

"The patient subsequently became more rational, but did not regain her power of speech; her paralysis continued; her bowels remained constipated; she passed urine involuntarily at times; her axillary temperature, taken daily, was always slightly higher on the paralyzed side. Two days before death she began to pass bloody

urine, and with a temperature of 99° F. she continued to fail, and died March 27th, on the twelfth day of her attack.

"The autopsy revealed in the brain considerable exudation of serum beneath the pia matter. Effusion of recently clotted blood was found in the left corpus striatum and optic thalamus, the brain-tissue about the clot being softened. Heart: Slight thickening of aortic and mitral valves. Lungs emphysematous; were moderately cedematous and congested. Liver and spleen were normal. Kidneys: In the left kidney the mucous membrane of the pelvis was reddened and inflamed and coated with blood; the kidney-tissue was atrophied, the pelvis and ureter dilated. In the right kidney the pelvis was enormously dilated and filled with fluid blood and urine. The mucous membrane of the pelvis was coated by recent exudation of fibrin and pus: the calyces were dilated, the kidney-tissue atrophied. Bladder: The mucous membrane was reddened, inflamed, and covered by exudation of fibrin and pus. Uterus: The posterior wall contained an enormous submural fibroid, which had increased in size so as to completely fill the cavity of the pelvis. It had undergone calcareous degeneration, being converted into bony tissue. The uterine tissue was stretched in a thin layer over its anterior surface. The cervix was normal, and the ovaries had preserved their normal relation to the fundus uteri, and were normal."

Dr. Heineman, on behalf of a candidate, presented a specimen which showed *several needles in the omentum*.

DR. BEVERLY ROBINSON presented a specimen, for which he was indebted to the courtesy of Dr. DeWitt C. Romaine, who also gave the following history and remarks:

PLACENTA WEIGHING THREE POUNDS IMMEDIATELY AFTER EXPULSION.

"The patient was born on an English vessel in the Atlantic Ocean, thirty-two years ago. Her previous history presented some points of unusual interest. During her girlhood she had always been delicate, was easily fatigued, suffered much from intense headaches, pains in her back, loins, and thighs; had a constant profuse leucorrhœal discharge, but *never menstruated*. Her mother, becoming alarmed at the absence of this function, consulted many physicians, who prescribed iron, quinine, and various other tonics, but all to no purpose. Although having never experienced a single monthly flow, she married at the age of nineteen, and bore her first child one year later, the weight of which was pronounced by the attending physician to be twelve pounds. Several months after this birth, the patient noticed that her leucorrhœal discharge increased in amount, once monthly, emitted an exceedingly offensive odor, and, as it issued from the vulva, presented a rust-colored appearance. These peculiar discharges occurred during a period of about eight months, when she again became pregnant, and was delivered in due time of her second child, whose weight, she says, was fifteen pounds. A third, fourth, fifth, sixth, and seventh birth occurred at intervals of little more than one year, the product of each being unusually large children. Her eighth confinement took place in November, 1881, when Dr. Romaine delivered her of a still-born child in an advanced state of putrefaction, the weight of which, taken immediately after birth, was ten pounds. Following this birth there was a period of seven months during which the patient enjoyed fairly good health, and the last four months of which she had a regular monthly flow having a duration of three days. This, she said, was the first time in her life that she had her courses as other women have them. She again became enceinte, for the ninth time, and was delivered by Dr. Romaine of her ninth child, with the forceps, March 23, 1883. The weight of this child was seven pounds, while the secundines, immediately after expulsion, weighed three pounds.

"Remarks.—The case is interesting with reference to four points :

"First.—Postponement of menstruation until several months after the birth of the first child.

"Second.—Menstruation occurring only twelve times in twelve years.

"Third.—Birth of nine children during a period of twelve years.

"Fourth.—Placenta weighing three pounds while child weighed but seven pounds."

STRICTURE OF THE URETHRA—CHRONIC DIFFUSE NEPHRITIS.

DR. FERGUSON presented specimens accompanied by the following history : The patient was a male, forty-four years of age, a native of the United States, and a book-binder by occupation. He had a stricture of the urethra for twenty years, for the relief of which he was operated on, by perineal section, four years ago. The wound never healed completely, and since that time he had retention of urine several times, symptoms of cystitis, and all the urine passed through the fistula which remained open after the operation. He was admitted into the St. Luke's Hospital on January 29, 1883. One month previous to this date he had several attacks of paroxysmal dyspnoea which were relieved by treatment.

On admission he had marked dyspnoea and cedema of the legs. Urine was 1.016, alkaline in reaction, and contained ten per cent. of the column of albumen. He was put on milk diet, acetate of potassium, and digitalis. He improved slowly and left the hospital much benefited by his treatment, passing sixty ounces of urine a day, on February 26th. He was readmitted on March 15th. He said soon after his return home the cedema reappeared, his urine became scanty, and he suffered from dyspnoea, constipation, and dyspepsia.

His urine at this time was 1.014 in specific gravity, alkaline in reaction, and contained thirty per cent. of albumen and many pus-cells. Treatment did not relieve his symptoms. On the 18th he showed evidence of mental derangement. Urine continued scanty and contained a large amount of albumen.

He failed gradually and died on March 27th. During the last week he was often delirious, both during the day and night. Toward the close pulmonary cedema developed, and he was comatose for several hours previous to his death. His temperature was always normal, his pulse 114, and respiration 32 per minute.

Autopsy on March 28, 1883. The vessels at the base of the brain were thickened, the brain was anæmic but otherwise normal. There were thirty-eight ounces of serum in the right pleural cavity, and eight ounces in the left. The heart was moderately hypertrophied. The lungs were congested and intensely cedematous. Kidneys : The right kidney was normal in size, its surface was granular, marking indistinct, and much fat in the convoluted tubules. The left kidney weighed only one ounce. Its surface was granular, both cortex and pyramids markedly atrophied and cystic. There is a close stricture of the left ureter, which admits a probe not quite one-sixteenth of an inch in diameter. The ureter above the stricture is moderately dilated. The right ureter is normal. The bladder is enormously hypertrophied and distended. The prostate gland is moderately hypertrophied. There is a stricture at the bulbo-membranous junction which does not admit the passage of any instrument. Anterior to this stricture the mucous membrane of the urethra is rough in places, and at certain points in the course of the tube its calibre is slightly narrowed. At a point one inch posterior to the stricture there is an opening in the floor of the urethra through which a probe passes downward and forward through the perineum. Externally this fistulous opening is at the junction of the scrotum and perineum, and admits a probe one-sixteenth of an inch in diameter.

The Society then went into executive Session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CONTAGIOUS DISEASES ACTS AND THEIR REPEAL—
DR. FARR—REWARDS TO MEDICAL MEN—MR. SPENCER
WELLS—OCCLUSION OF CEREBRAL VESSELS BY OIL.

LONDON, April 21, 1883.

A bomb-shell has fallen among the ranks of those who support the Contagious Diseases Acts of 1866 and 1869. Mr. Stansfeld's motion in the House of Commons last night, to the effect that the House disapproved of the compulsory enforcement of the Acts, was carried by a majority of 72—the numbers being, for the motion, 182; against, 110. Such a large majority could scarcely have been anticipated, even by the most sanguine enemies of the Acts, but the fact of the Government being divided in opinion amongst themselves probably gave considerable encouragement to the abolition party. Mr. Gladstone was not present, but his son (Mr. Herbert Gladstone) voted with the majority. None of the medical members spoke on either side. As a body, the profession is certainly in favor of the Acts as they now stand, on the ground that they have undoubtedly lessened disease. A few medical men are against the Acts, and of late public opinion has been growing against them, chiefly on moral grounds. The various religious organizations have done a good deal to foment an agitation against them. Many army surgeons and chaplains are of opinion that not only are the Acts hygienically satisfactory, but that they have actually lessened immorality in the districts where they are in force, especially juvenile prostitution. The opinion of the House of Commons as expressed last night is doubtless the death-knell of the Acts, at any rate in their present form. Legislation is slow in this country, so a change in the law is hardly to be expected this session, which is perhaps fortunate, as it will give time to members to consider the subject more carefully. It is satisfactory to find that the Acts have, in general, been carried out carefully, and without any of the brutalities of which the French police have been guilty. Some of the latter, described in this month's number of the *Westminster Review*, are positively sickening.

Death has again been busy amongst us. One of its latest victims is Dr. William Farr, who has just died at the ripe age of seventy-five. In him has passed away one who may justly be described as the founder of our present system of "Returns by the Registrar-General." The importance of this work it would be difficult to exaggerate. Almost all our present knowledge of vital statistics is due to Dr. Farr. Our insurance companies owe him an immense debt of gratitude, for he placed no key upon his knowledge, but the results of his enquiries were published for the free use of all, and from the information supplied in Dr. Farr's tables many of them have constructed their scales. The head of the statistical department, he was for many years regarded as the virtual "Registrar-General," the latter post being merely a sinecure, and when a few years since the post became vacant, and Dr. Farr applied for it, loud and widespread was the indignation amongst the profession that Dr. Farr should be grudged his well-earned reward. The office was bestowed on a political puppet, and Dr. Farr retired from the work which he had founded and successfully carried on for so many years. The only honor he ever received was a paltry C.B., a dignity which, when bestowed, seldom leads to anything higher. Dr. Farr was not merely a government official; he was in early life a journalist and contributed several papers to the literature of hygiene. A testimonial was got up by public subscription and presented to him on the occasion of his retirement from public life.

Curiously enough, in the very week of his funeral a discussion on rewards for public services has been going on in the Houses of Parliament, the occasion being the

Egyptian campaign and its leaders. The profession has always complained of imperfect recognition, and when as now, a medical man receives some honor or reward it is usually the case that the favored recipient is the holder of some Court appointment, and is thus brought into contact with those who prefer a medical attendant with a handle to his name. Such is the case with Mr. Spencer Wells, who has just received a baronetcy. Mr. Wells is now President of the English College of Surgeons, and no one will grudge him his reward for much good work in the past. It is, however, a significant fact that he is also Surgeon to the Queen's Household.

At the last meeting of the Pathological Society, Dr. Handfield Jones exhibited some microscopic specimens which excited some interest, and to examine which a special committee has been appointed. They seemed to show that atheroma of the larger cerebral vessels may lead to blocking of the smaller, by globules of oil.

OUR PARIS LETTER.

TYPHOID FEVER—RESTRAINT UNDER PRETENCE OF INSANITY.

(From our Special Correspondent.)

PARIS, April 13, 1883.

THE long and yet inexhaustible discussion on typhoid fever at the Academy of Medicine has at last been brought to a close, but before it was so it had merged into a war against microbes, and in the *mêlée* poor M. Pasteur was rather severely handled. Professor Peter led the attack and contested the correctness of M. Pasteur's views respecting his inoculation for the mitigation or prevention of certain diseases, as they were performed under circumstances so different and on animals so dissimilable in their nature. Moreover, they could not stand the test of clinical experience in human medicine, whatever may be the results among the lower animals. Even among the latter, he said, it was questionable whether inoculations as practised by M. Pasteur were of any real value, as, to acquire a certain amount of immunity, it was necessary that the inoculations should be performed at short intervals, and during the whole lifetime of the subject. Besides which, Professor Peter did not believe that the microbes were the real agents of disease; that is, they had no pathogenetic power inherent in themselves, but that they were the simple vehicles of virulent or infectious diseases, so that the same microbe may transmit different diseases in passing from one organism to another. M. Bouley, the eminent Professor of Veterinary Medicine, stood up as the champion of Pasteur's views, and although he was most eloquent in his response to Professor Peter, yet it cannot be said that his arguments were sufficiently convincing, and the Academy, weary, no doubt, of the interminable discussion on typhoid fever, has appointed a commission to formulate conclusions, which simply means they have had enough on the subject, and I think your readers too.

In continuing their researches on the inherent properties of oxygenated water, or the peroxide of hydrogen, on the animal organism, which has been proved to possess antifermentative or antiseptic properties, MM. Paul Bert and Regnard lately submitted a paper at the Biological Society, demonstrating the action of oxygenated water on albuminoid substances, and found that when shaken together with the white of egg the latter becomes incoagulable by heat, but retains its coagulability by the other agents of coagulation. The substance thus formed constitutes a variety of albuminose, which behaves like albumen, but only in a minor degree. The same result is obtained with the albumen of the blood. In treating fibrin with oxygenated water, the new substance becomes incoagulable by heat or nitric acid, but coagulable by the other agents of coagulation. This, then, is a new modification of albuminoid substances, and the authors expressed a hope that these results will induce chemists to make further researches and

be able to explain the different properties of albuminoid substances, which will prove of great value in the diagnosis and therapeutics of certain affections.

A recent "cause célèbre" of illegal or unjustifiable "sequestration" has created some sensation in this country, on account of a young lady who was removed by force from her own home and placed in a "Maison de Sante," or private asylum, under the pretence of insanity, to which effect a certificate was given by an ordinary physician. The case was brought before the police court, and Dr. Legrand du Saulle, one of the leading alienists of this country, was directed to re-examine the presumed lunatic. The purport of Dr. Legrand du Saulle's report did not quite refute the tenor of the medical man's certificate, but he asserted that, although the mental condition of the patient was below the normal, yet it did not necessitate her being removed to a lunatic asylum. The young lady was in consequence set at liberty and the charge of illegal sequestration was brought against those who were concerned in the act. The medical man who signed the certificate was severely reprimanded for having acted with such levity, as the certificate was granted only on one visit, which lasted but a few minutes. The principal agents have been remanded for the Court of Assizes, as sequestration is considered not a misdemeanor but a crime, the police court being therefore incompetent to give judgment in the case. This unsatisfactory state of things drew the attention of the authorities to the law of 1838, which is considered very defective. According to this law any citizen, on the simple certificate of a physician, whether he be the regular medical attendant or not, may be confined in a mad-house. It is said that the tenor of the law referred to gives the doctors too great latitude, as the power thus vested in them may be abused. No doubt it has been, as in the case under notice, and will be again, but it is the opinion of some alienists, that however lax that law may appear, yet it is not sufficiently rigid, as there are a great number of lunatics at liberty whose place would be better in an asylum. Dr. Legrand du Saulle, a high authority on the subject, has calculated that there are twelve hundred lunatics who go about the streets at the present moment, and in a very interesting work by the same author he made the startling statement that three-fourths of those who spoke at public meetings, particularly of a political character, were not of sound mind. For instance, a great number of the "communists" were insane or on the border-land of insanity, as shown by their acts, and whether insanity is contagious or not, there can be no doubt that, judging from recent events, there are other people besides French communists or anarchists who are manifestly affected with the malady.

In connection with the above I may mention that Dr. Legrand Du Saulle has been appointed principal physician to the infirmary for lunatics attached to the Prefecture of Police, in the room of Dr. Laségue deceased. This infirmary is intended for the reception of people out of their mind, whether they are really or only suspected to be so. Here they are detained for twenty-four hours, during which time they are visited by the physician and disposed of according to circumstances. It appears from a report lately published that, on an average, there are three thousand individuals who are annually taken to this infirmary.

ANÆSTHESIA FROM GALVANIZATION OF THE SUPERIOR LARYNGEAL NERVE.—Brown-Séquard states that it is sometimes possible to produce complete general anæsthesia by galvanization of the superior laryngeal nerve. In the anæsthesia as produced in a dog, irritation of the brachial plexus elicited no expression of pain. Another effect of galvanization of this nerve is an extraordinary acceleration of the respiratory movements. At the moment of the irritation of the nerve, the respiration, which was calm and slow, counting about 12 to the minute, suddenly rose to 120 or 130 respirations per minute.—*La Tribune Médicale*, March 11, 1883.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 21, 1883, to April 28, 1883.

CLEARY, PETER J. A., Major and Surgeon. So much of par. 10, S. O. 273, November 23, 1882, from this office as directs him (then captain and assistant surgeon) to report in person to the Commanding General, Department of Dakota, is revoked, and upon the expiration of his present sick leave of absence, to report in person for assignment to duty in the Department of the Missouri. S. O. 95, A. G. O., April 25, 1883.

HOPKINS, WM. E., First Lieutenant and Assistant Surgeon. Now on leave of absence in New York City, to be relieved from duty in the Department of the East, and assigned to duty in the Department of Arizona. S. O. 95, par. 7, A. G. O., April 25, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending April 28, 1883.

PARKER, J. B., Surgeon, ordered to the Torpedo Station, Newport, R. I., vice Surgeon WM. J. SIMON, detached and waiting orders.

SIMON, M. H., Passed Assistant Surgeon, detached from the Naval Hospital, Chelsea, Mass., and ordered to the Naval Hospital, Yokohama, Japan, vice Passed Assistant Surgeon C. BIDDLE, detached and ordered to the Richmond.

AUSTIN, A. A., Passed Assistant Surgeon, from the Richmond and ordered home.

BRYAN, J. H., Assistant Surgeon, ordered to report May 1st for examination for promotion.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending May 1, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
April 24, 1883.....	17	6	141	5	166	51	2	0
May 1, 1883.....	13	7	153	4	167	54	2	0
<i>Deaths.</i>								
April 24, 1883.....	0	2	20	3	26	26	1	0
May 1, 1883.....	1	3	23	4	22	17	1	0

Of the few cases of small-pox occurring this year, an unusually large proportion have been either of the confluent or hemorrhagic variety, causing a proportionally large death-rate. Twenty-one cases of typhus removed from St. Stephens Home up to May 1st.

Whole number of deaths reported for week ending April 21st, 630, of which 84 were from pneumonia.

ALUMNI ASSOCIATION OF BELLEVUE HOSPITAL MEDICAL COLLEGE.—At the annual meeting, held at the College on April 21st, the following officers were elected for the ensuing year: *President*, F. A. Castle (re-elected); *First Vice-President*, V. P. Gibney; *Second Vice-President*, W. T. Alexander; *Recording Secretary*, R. Van Santvoord; *Corresponding Secretary*, R. Newman; *Treasurer*, W. H. Katzenbach; *Historian*, F. A. Castle.

Managers to serve until 1884: J. D. Bryant, F. A. Castle, W. A. Ewing, F. E. Hyde, G. R. Kent, W. T. Lusk, R. Newman, J. R. Taylor, C. Terriberry, R. M. Wyckoff. *To serve until 1885*: E. S. Bunker, L. J. Godon, G. Griswold, E. M. Lyon, E. A. Maxwell, J. B. Messemer, J. J. Van Voorst, W. R. Varick, D. L. Wallace, T. Wilde. *To serve until 1886*: G. W. Bull, T. H. Burchard, V. P. Gibney, E. C. Harwood, A. M. Jacobus, C. A. Leale, A. V. B. Lockrow, L. H. Sayre, A. A. Smith, L. M. Yale. *To serve until 1887*: W. T. Alexander, F. H. Bosworth, F. S. Dennis, W. H. Katzenbach, S. N. Leo, J. P. Munn, L. Putzel, G. H. Swezey, R. Van Santvoord, W. G. Wylie.

THE HANDS AND MUSCLES OF PRIZE-FIGHTERS.—A trainer and sporting man discusses in the *Sun* the subject of prize-fighters' hands: "I have seen, in my experience, that the smaller the hand, if in proper condition, the more execution it does as a general thing, particularly in dealing chopping blows. A small, hard hand often cuts like a knife, whereas powerful, big hands and huge muscles behind them may knock a man down without hurting him much. And this thing of getting up very big muscles is liable to be carried to extremes, and to do more harm than good. The training and development of muscle has a tendency to draw up and tighten the sinews, and to make the muscles act more slowly. What a pugilist needs is quick, natural muscle, and small, hard hands for it to punish with. Heenan's hands were of quite a moderate size, and would have been small but for the blacksmithing work he did in his youth. That spread them. Yankee Sullivan had a very small hand and a small arm, but there wasn't a wicked fighter in the world. He was really an eleven-stone man when in condition, though he looked like a man of twelve stone. John Morrissey had a good-sized hand and short arms. But he wasn't any criterion to go by in any way. Tom Hyer did not have a large hand in proportion to his size. He was six feet two inches, you know, in height, one of the most formidable-looking men ever seen, and, for his size, his hand was even small.

"It is a very important thing to get the hands in good condition before a fight. To do that if they are pulpy and soft, we sweat them as much as possible and rub them, to work off the superfluous flesh and fatty tissue. Then, about two weeks before the time for the fight, we begin pickling the hands. This is deferred as long as possible because it is a very disagreeable operation. It gives a very disagreeable feeling to the hands, and if you incautiously touch your eyes with fingers that are undergoing the pickling process, you will hurt them severely. The pickle is composed of vinegar, alum, horseradish, saltpetre, and tan water, all boiled together. When a man's hands were inclined to be very fleshy, we used to put in a little copperas also, which cuts down the flesh very rapidly. That, however, was only in extreme cases. When a man has come in from his afternoon exercise, had his bath, rub down, and supper, then for a while before he goes to bed he has to sit and soak his hands in a pot of that pickle, rubbing them hard at the same time. Soon they get hard and almost as rough as a nutmeg grater. Once a day is enough. It takes some time after the operation for the hands to get fleshy and soft again, much longer than it does to bleach them to a decent color again."

BLEEDING COUP-SUR-COUP IN PNEUMONIA.—Not long ago Professor Hardy, in his clinic at La Charité, protested against the unreasonable prejudice against all venesection which has taken the place of its former extravagant adoption. His audience seemed almost astonished at his presenting to them a case in which he had performed bleeding for pneumonia three times in the twenty-four hours, and that in the very theatre in which Bonillaud formerly so warmly advocated the *coup-sur-coup* practice, since almost forgotten. The subject of the case was a man of thirty-seven years of age, of good constitution, and in the enjoyment of good health until four

days prior to admission with well-marked signs of acute, fibrinous, lobar pneumonia of the left side. In presence of this case of uncomplicated pneumonia occurring in a man in the prime of life and of good health, and who had no morbid antecedents except two similar attacks some years before, Professor Hardy ordered 400 grammes of blood to be drawn at once, 400 in the evening, and 300 next morning, so that 1,100 grammes were taken in the twenty-four hours, and a somewhat abundant epistaxis followed some time after the last venesection. After the third bleeding the condition of the patient was greatly improved. The oppression of the breathing was relieved, and the cough and expectoration were sensibly modified, the temperature descending first to 39° and then to 38° Cent. Next day all fever had entirely ceased, the temperature being 36.8° , the pulse 80, and the respiration 18; the cough had disappeared, and the expectoration, which persisted awhile, was white and fluid. The local signs decreased in like manner, so that on the second day there scarcely remained a slight dulness and obscurity of respiratory sound at the base, respiration being quite normal throughout the rest of the lung. This rapid disappearance of the local signs was, in fact, one of the most special and remarkable facts of the case, when we remember how frequently such signs are found to persist for several days after the complete disappearance of fever and the general symptoms. In this case the disappearance was almost simultaneous; and Professor Hardy attributes this favorable result to the bleedings practised after the method of his great predecessor. But while treating the patient in this manner, Professor Hardy had the case of a colleague under treatment, in which the conditions of the patient's general state and local lesion were quite different, and in which blistering, Todd's alcoholic mixture, tonics and reconstituents were the means required, and were followed by complete success.—*Medical Times and Gazette*.

DIET AND RESISTANCES TO INFECTION.—Professor Feser, of Munich, has been making some examinations on animals, with a view to establishing the connection believed to exist between diet and the liability to infection. In the trials he has made on rats inoculated with the poison of cattle distemper, he demonstrated the fact that the animals which had been fed upon a vegetable diet were quickly attacked by the disease, while those which had been fed exclusively on meat resisted the effects of the inoculation. In recording this fact, a leading English journal in connection with the European leather trade, attributes to the greater amount of vegetable diet, in the shape of bread, beer, etc., taken by wool-sorters between Saturday and Monday the greater frequency of cases of outbreak and the aggravation of disease during this period. We fear that the above theories will not hold good when widely applied to man.

EXPERIENCES OF THE NAVAL MEDICAL DEPARTMENT WITH SOME NEW REMEDIES.—In the spring of 1882 the Bureau of Medicine and Surgery distributed a number of new remedies to various stations with the request that they be tried and the results reported. The following report was given regarding some of them by Dr. Hudson, at a meeting of the Naval Medical Society:

Cascara Sagrada.—Dr. Dean, Naval Hospital, Philadelphia, reports: "This is a reliable and unirritating laxative and cathartic, but the fluid extract is nauseous and objectionable; the cordial is, however, much less so." Dr. Gorgas, Naval Academy, says: "It is a certain cathartic, and in small doses an excellent laxative. In a case of chronic constipation in a child of four years this remedy afforded perfect relief." Dr. Bloodgood, Naval Hospital, New York, observes: "It possesses undoubted virtues as a mild cathartic, and is not of unpleasant taste."

Cascara Amarga.—Dr. Bloodgood has tried this in several cases of consecutive syphilis, but without any perceptible results.

Stigmata Maidis.—Dr. Dean reports that this was tried in several cases of chronic cystitis, and, while they were not cured, the results were favorable in mitigating the severity of the symptoms. Dr. Gorgas was able to speak very highly of it as a demulcent and diuretic. Dr. Bloodgood states that in cases of acute and chronic cystitis its action was not remarkable.

Quebracho.—Dr. Gorgas used this remedy in several cases of asthma, and in one only was there marked benefit, but the relief here was immediate and complete. Dr. Dean states that temporary relief followed in some cases, while in others there was no result. Dr. Bloodgood found that in cases of cardiac hypertrophy, with dyspnoea, in which it was tried, there was no relief.

Piscidia Erythrina (Jamaica Dogwood).—Dr. Sudards, Naval Hospital, Norfolk, Va., finds this agent to be slightly anodyne in its effects in mild cases of neuralgia, and in large doses it produces sleep. Dr. Dean tried it in three cases in full doses; no effect in two, and sleep induced in the third; it did not appear reliable as a hypnotic. Dr. Bloodgood found only negative results.

Yerba Santa.—Tried by Dr. Dean in several cases of chronic bronchitis and asthma, with no decided benefit. Dr. Bloodgood reports like results in cases of chronic pneumonia and secondary syphilis.

Manaca.—Dr. Bloodgood states that this was carefully tried in cases of chronic rheumatism. Full doses produced severe headache, diarrhoea, tenesmus, and bloody stools, but there were no beneficial results.

Sanguis Bovis Exsiccata.—This was tried by Drs. Dean and Bloodgood without benefit; the latter reporting nausea from its use.

ANGINA PECTORIS SUCCESSFULLY TREATED WITH NITRO-GLYCERINE.—Dr. Jacob Frank, of Buffalo, N. Y., relates the history of a married woman, aged thirty-one, mother of three healthy children, who had for six years suffered intensely from attacks of angina pectoris. Dr. Frank does not say whether there was any organic heart trouble. She was treated with morphine and various other remedies, but without success. Dr. Frank at first applied the faradic current over the pneumogastric, and got relief. During the next attack, however, this failed. The patient was then put upon nitro-glycerine, $\mathfrak{M}\mathfrak{j}$. of the one per cent. solution gradually increased to $\mathfrak{M}\mathfrak{v}\mathfrak{j}$, t. i. d.; then decreased. The patient has had no further attack. Dr. Frank writes: "During the course of this treatment a rather curious phenomenon occurred. After she had been taking this nitro-glycerine for about six weeks, aphthae broke out on the tongue, mouth, and fauces. The medicine was stopped, and these ulcers treated with borax, etc., after which the treatment was again resumed." Dr. Frank gives the usual explanation of the curative action of the drug.

LOUISVILLE SCHOOL OF PHARMACY FOR WOMEN.—Dr. J. P. Barnum writes us that there is a school of pharmacy for women in Louisville, and that it is well endorsed, and has already a fair attendance. He further writes: "The object of the school is to thoroughly educate women as practical apothecaries, and by this means open to them another avenue by which they may obtain a livelihood. That woman is eminently fitted for this business the writer can testify from personal experience, having made the practical test in his own business. He has found female assistants equal to those of the other sex in everything except physical strength, while they are very far superior in delicacy of manipulation, accuracy, and neatness in a multitude of details, which tend to make the prescription either attractive or unpleasant to the eye, and agreeable or nauseous to the palate of the sick."

THE TREATMENT OF ERYSIPELAS WITH WHITE-LEAD PAINT.—Dr. William W. Reese, Brooklyn, N. Y., writes: "A note on page 420 (from *The Lancet*) of the last number of THE MEDICAL RECORD (April 14th), on the treatment of erysipelas with 'white lead paint,' suggests to me to give some of my experience also with this local ap-

plication during the past fifteen or eighteen years, which may possibly induce some other practitioners to give the benefit of the treatment to their patients, as well as save themselves some solicitude at times and a good deal of trouble.

"Reasoning as to the sedative and other properties of the carbonate of lead and the peculiar character of the diseased surface, I began the local application of the article, in a case of the disease developed on the face and head, with a patient about sixteen years old; and have continued to employ it in all cases since, whether idiopathic or traumatic, and invariably with satisfactory results, in ages varying from that already mentioned to over seventy years—not, of course, disregarding the indications pretty generally to be observed for the employment of a mercurial purgative in the beginning and tonics subsequently.

"The lead mentioned must be ground up very finely with flaxseed oil *only*, and after the manner of house-carpenters, and applied with a soft brush over and a little beyond the affected surface of both face and head, and renewed whenever it should get rubbed off. There need not be any fear of injurious absorption *through* the diseased skin. Unless the hair on the head be very thick, it need not be thinned for the purpose of applying the paint. As evidence that the lead will not injure the hair (a consideration or fear that might create resistance with some persons), one patient, who was over seventy years of age, and had had a very thin crop on the top of the head, exhibited, some months after getting well, a greatly increased supply, and of his own growth."

Dr. N. O. D. Parks, of Ashton, R. I., writes: "Two days after reading in *The Lancet* the article to which you refer in your last issue from Mr. Barnwell, of Charing Cross Hospital, London, on 'Rapid and Successful Treatment of Erysipelas,' I was called to a child, who about a week previously had received a burn on the back of the right hand. When I saw him there was a sore about the size of a silver dime, from which started a dusky erysipelatous blush all over the hand and about two-thirds up the back of the forearm, partially encircling it in front with great swelling and fever and intense pain in the affected part. Tongue very foul, temperature 101.4°; pulse, 108. I painted the entire reddened surface, and about three inches beyond, with a thick coating of white-lead paint, enveloped the limb in cotton-wool, and prescribed tinct. ferri chlor. The next morning I was delighted to find the child playing about, tongue clean, temperature 97°, pulse 84, and he has continued well ever since.

"A writer in a subsequent number of *The Lancet* calls attention to the fact that this treatment is by no means new, at least as relates to burns and scalds, and refers to Wood & Bache's United States Dispensatory (1858, p. 601), where will be found the following: 'It (plumbi carbonas) is recommended for scalds and burns by Professor Gross; and Dr. Henry, of Iowa, bears testimony to its efficacy. The white lead is first brought to the consistency of cream by linseed oil, as in making common white paint, and then brushed over the inflamed surface. Its external use, however, is viewed by many practitioners as dangerous, on account of the risk of absorption, but the occurrence of bad effects is rare.'

"It will be seen that I did not trust to the efficacy of the white-lead paint alone, but I think the rapidity of the cure may be justly attributed to it."

THE PAPER ANGEL CASE.—The case of Miss Gannon and the paper angels, which has lately come up in the courts again, was described in full in *THE RECORD* some time ago. It illustrated a curious form of hysteria, combined probably with the hypnotic state.

REPORT OF TWENTY-NINE CASES OF TYPHOID FEVER.—Dr. J. T. Deemer, of Manorville, Pa., sends us the notes regarding twenty-nine cases of typhoid fever treated by him in private practice during the past year. All the

cases were either of severe or medium type of severity. The *mortality* was three, or about ten per cent., which is a favorable showing. The deaths were, one from perforation of the bowels, two from exhaustion. They occurred in cases above the age of twenty years.

Relapses occurred in three cases. Of the twenty-nine cases twenty were adults.

Hemorrhages occurred in several cases. In two cases there were seven hemorrhages, but recovery took place under the use of ergot and turpentine.

Persistent diarrhoea was met with in two cases, of which one died. The other recovered under the use of morphine and sulphate of copper.

Ordinarily for the diarrhoea bismuth, with a little opium controlled, was sufficient. In both cases of bad diarrhoea, beef-essence had to be discarded.

Tympanites was present in about two-thirds of the cases, for this turpentine emulsion was used with good effect.

The *temperature* ranged in most cases from 102° F. to 105° F. The treatment for reducing the temperature was quinine and mineral acid, with sponging morning and evening. The mode of exhibition of quinine was about two grains every second hour, combined with either nitro-muriatic or arom. sulph. acids.

Stimulants were used in nearly every case, from four to eight ounces of whiskey in twenty-four hours, as indicated by the heart's action. Whiskey and brandy were preferred. Wines being too bulky. The diet consisted of beef-essence, rice, water, tapioca, milk, etc.

In the most cases quinine acted most happily, in a few cases it seemed to cause cerebral trouble.

One case was complicated with *articular rheumatism*. In this case there were no cardiac symptoms of rheumatism. Salicylic acid and quinine were used, and the case recovered after a lingering illness. One case was complicated with *pneumonia*, but the patient recovered.

Three cases were complicated with *bronchitis*, one of these was one of the fatal cases before enumerated. The local applications to the bowels used were inunctions, with lard and turpentine, in some cases where much tenderness existed, light warm poultices were applied.

The causes seemed clearly traceable to bad drinking-water, which undoubtedly was contaminated with fecal impurities from privies in close proximity to the wells from which the water was obtained. Two nurses contracted the disease.

The above treatment has been compared side by side with other modes of treatment in the hands of other physicians, and has been found to yield as good results as any.

A CORRECTION.—The name of the author of the article entitled "A Novel Mode of Cleansing the Vault of the Pharynx," published in *THE RECORD* of April 28th, was by mistake printed Dr. G. Fairfax Whitney, instead of Whiting, as it should be.

We have been requested to insert the following as a special favor to the signers:

"TO THE MEDICAL PROFESSION OF THE STATE OF NEW YORK:—We, the undersigned, ex-presidents of the New York Academy of Medicine, desire to record our approval of the action taken by the Academy at the Stated Meeting of April 19, 1883, reaffirming the ethical clause of its by-laws, and our indorsement of the course pursued, by request of the Council of the Central Organization of the New York State Medical Association as presented at this meeting by Dr. Austin Flint, Jr. WILLARD PARKER, M.D., President New York Academy of Medicine, 1856.

JAMES ANDERSON, M.D., President New York Academy of Medicine, 1861 to 1867.

AUSTIN FLINT, M.D., President New York Academy of Medicine, 1873 to 1875.

SAMUEL S. PURPLE, M.D., President New York Academy of Medicine, 1875 to 1879.

NEW YORK, April 30, 1883."

Original Lectures.

THE DETERMINATION, BY THE GENERAL PRACTITIONER, OF THE NECESSITY FOR WEARING GLASSES.¹

By D. B. ST. JOHN ROOSA, M.D., LL.D.,

PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL; PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE UNIVERSITY OF VERMONT.

LECTURE I.

GENTLEMEN—I suppose that most of you will be general practitioners of medicine. Even if some of you are to become specialists, you will be general practitioners for some time before you enter upon special practice. As general practitioners you desire to know the things which are essential to the successful filling of such a position. Some of this knowledge I attempt to teach in the ophthalmological course in this college. To-day I begin a series of three lectures on the conditions of the eye which require the use of glasses. I propose to speak only in a way in which the average general practitioner may fully understand. You may, therefore, dismiss from your minds any notion that I am lecturing to men who have already taken some instruction in ophthalmology, or who have attended special courses of instruction in hospitals where diseases of the eye are treated.

I presume only, that you are medical students of one or more year's standing, that each one of you has a knowledge of the anatomy of the eye, that all of you have a general knowledge of its physiology, and that each one of you knows something of the laws of light as at present understood.

If you are deficient in any of these respects, these lectures, whatever they may accomplish under other circumstances, will do you but little good. He who knows nothing whatever of the theory of the manner in which undulations of the atmosphere produce what is called light; who knows nothing about the bending of rays of light when they pass from one medium into another; who knows nothing about the cornea, sclerotic, optic nerve entrance, the retina, and so on, will profit but little from what I shall have to say. It is in the attitude of a good general student that I expect the hearer to stand, and I hope he will go out from these three lectures enabled to give a correct opinion in a given case as to whether or not the patient would probably be benefited by properly chosen spectacles.

The necessary apparatus for the oculist embraces quite a large variety of glasses. I have brought my working-case here simply for the purpose of showing to you what is used by those who make diseases of the eyes a specialty. I do not expect that you will attempt to use one so large. Here it is, as it is in daily use. With it we may correct every impairment of vision that is dependent upon an error in refraction or accommodation of the eye.

On this side is a set of concave glasses extending from those of two inches focal distance to those of sixty inches focal distance. On this side is a set of convex lenses. Here is a series of prisms ranging from two degrees to fourteen degrees. Here is a disk with a small central aperture, and here is one without the central

opening. Here is a colored glass. Here is a tape measure.

There is a frame for holding a pair of glasses, and here is one for holding two pairs of glasses, so that we are able to make combinations, change the axis of the glasses, and so forth. Then there is a series of the lenses not ground from spheres, but from cylinders, cylindrical glasses, glasses for correcting the defect of vision known as astigmatism. With these you have, so far as glasses go, an outfit for the man who wishes to correctly fit any conditions of the eyes that may require spectacles. But we will put this large case aside. We do not need it for our present purpose. It will be impossible for the general practitioner to equip himself with sphygmographs, ophthalmoscopes, laryngoscopes, test-glasses, and all the appliances which the knowledge of the nineteenth century has rendered necessary for special experts. You will, however, have no right to the name of good general practitioners, unless you are able to say, in a given case, whether it be one of hypermetropia, myopia, presbyopia, or amblyopia.

Let us study the case before us and from it learn the method by which you are to work. You will go to your village where you are to begin the practice of medicine, and where there is no specialist. Let us suppose that a woman brings her child to you for some examination with regard to its eyes. You shake your head at once as you see that the eyes are not red, there is no opacity of the cornea, the pupils are movable, and you say, "Madam, I do not know anything about eyes, and I prefer not to meddle with them."

"But, Doctor, do you think I can do anything for my child? What shall I do? She cannot see as well as the rest of the children. Do you think she is going to be blind?" You will find it to your advantage and it will add to your self-respect to be able to answer these questions, and you should be able to do so correctly, and put your would-be patient's mind at rest.

You will have in your office a set of test-types, for you can get these by an expenditure of twenty-five cents. I will show you a sample. I will not attempt to tell you the history of these test-types; that you can find in any of the special books on affections of the eyes. They are known as Snellen's test-types, from the name of the distinguished Dutch oculist who provided them for the profession. You will assume from what you have heard and what is stated in the books that this large letter "A" should be seen at a distance of two hundred feet, by a person whose vision is normal. The letter in the next line should be seen at a distance of one hundred feet, and so on until you reach the bottom line of letters, and that should be read at a distance of twenty feet. Here, then, you have an arrangement by means of which you can find out whether or not there is any loss of vision. This is the first step to be taken in the examination, no matter what the defect in vision may actually be. Persons are often said to be blind when they see moderately well, and are said to see very well when they see very badly, or scarcely at all, but with a card like this hung up across the room at the distance of twenty feet or less, you will be able to determine accurately whether or not the vision in a given case is deficient. You may not have a room twenty feet long. If not, perhaps an adjoining hall may be added, or you may apply the test at the distance of sixteen or even twelve feet; but these are difficulties which will quickly be overcome if you are in earnest concerning

¹ Delivered at the University Medical College, Session of 1881-82.

your investigation. The state of bewilderment some general practitioners are in when examination of an eye is mentioned, is only to be compared to the dismay which comes over the mariner when he finds himself in a dense fog, and when he fears that the next moment he may run upon the shore. There is no need for this bewilderment. The means for learning these things about the eyes are perfectly simple. All that is necessary is a well-lighted room, a set of test-types, and a patient complaining of his or her eyes, and we are ready to begin a scientific investigation of the vision.

Our little patient's name is Maggie; she is twelve years of age. Let us allow her to tell her own story. She complains of pains in her eyes, which come once in a while through the day. They generally occur when she is reading and studying, for she is a school-girl. Without doubt the same pains would occur were she writing or sewing, or doing any similar work which engaged the eyes steadily.

She recollects that her eyes began to pain her about two years ago, but does not remember whether they troubled her before that time or not. She locates the pain in what we know as the *orbicularis palpebrarum* muscle. She says that her eyes begin to pain her whenever she looks at her book or any near object for ten or fifteen minutes.

We will first do what should always be done in every case, namely, inspect the eyes. The eyelashes are perfectly free from secretion. The cornea is perfectly clear. I shut her eyelid over the eyeball, and then remove it and allow the light to come in quickly, and I see that the pupil moves. I evert the lids and find that they are healthy. Her eyes, then, are apparently, to the external view, normal, and yet she complains that she cannot use them steadily for any length of time without suffering pain. We have found a symptom, and only a symptom. That symptom is pain upon any continued use of the eyes. It has existed more or less for two years, and occurs chiefly when the little patient attempts to read. The name of that symptom is *asthenopia*, or weak sight. The definition of *asthenopia* is inability to read, write, sew, etc., continually without pain or discomfort. Thus we have gone in a circle. What is the cause of this *asthenopia*? Can we find it out? If so, how? You might say: "I cannot go any further; it will probably require the ophthalmoscope to ascertain the condition of the eyes. Doubtless she has commencing atrophy of the optic nerve; or amaurosis; or, forgetting that young people seldom have glaucoma, you may say perhaps this is a case of glaucoma, and you only breathe with freedom when some specialist or some other general practitioner assumes the responsibility of the case." But suppose you do not say so; and on the contrary assume that the probable cause of this *asthenopia* can be determined without a knowledge of the ophthalmoscope, or the appearance of the optic nerve or of the retina. At any rate, let us see how far we can go without these instruments of precision. In the first place we will measure twenty feet from this chair where Maggie will sit, and at that point the card on which are Snellen's test-types will be held. I ask in this instance that twenty feet be measured in order to carry out the form of examination with absolute correctness and see whether this patient can read the bottom line of letters at this distance.

But, after all, it is only approximately correct. There are but few absolute truths in this world. There are but few statements which are not modified by circumstances. For example, I hold in my hand another test-type in which the letters are of the same size as in Snellen's, but they are a little closer together, and, as a matter of experience, it is a little more difficult to see them at a distance of twenty feet; but I will not dilate upon this trifling fact, because it may lead to confusion in your minds.

Can a given patient have a very serious disease of the back part of the eye, considerable optic-nerve or retinal trouble, and still be able to read the letters in the

lower line at the distance of twenty feet, or, as oculists say, who has vision $\frac{20}{20}$ or normal? We may safely answer this question in the negative, and say that, as a rule, these conditions being fulfilled, there is no serious disease of the back part of the eye, nor of the refracting media, the cornea, or the lens, or the vitreous. Yet this, after all, is a statement which is only approximately true. It is generally true. The exceptional cases which you will occasionally meet with you will soon learn to place by the side of these ordinary ones, and you will soon come to the making of a correct diagnosis in them. We will therefore assume, as a general rule, that a person who can read $\frac{20}{20}$ has perfect vision, and we may exclude disease at the back part of the eye. We have already assumed that you do not use the ophthalmoscope, and we shall not be able to go further without this assumption.

It is essential in this scientific experiment, as in all others, to exclude, so far as can be done, all possible sources of error. It is a wise thing, therefore, not to keep these test-types hung where the child can see them, even for the five or ten minutes that you are conversing with the mother or friend, for a bright child may learn all these letters within that space of time, and when you come to your testing, may assume to read them readily at any distance.

It is also proper to test each eye separately, because the eyes may not be alike. We will therefore cover Maggie's left eye by holding a bit of pasteboard closely in front of it, and then ask her to read. [The patient reads.] She reads all these letters readily at the distance of twenty feet, and we can say, so far as the right eye is concerned, that she has no serious disease at the back part of it. The vision of the right eye is normal: V. R. E., $\frac{20}{20}$. [The right eye was then covered, and the patient asked to read letters in different lines at random, in order to avoid the possible error of having committed them to memory.] The vision of the left eye is normal: V. L. E., $\frac{20}{20}$.

We are now no further in our study of the case than we were before, except that we are able to say that the child has no very serious disease at the back part of the eye, and she is not going to be blind from her present trouble. These are certainly somewhat important facts. Let us take another step. We have been told that there is a condition of the eyeball in which it is too short from before backward. You have already seen a diagram by which lectures upon this condition have been illustrated, and here you may see it again.

You have been told that the rays of light which come from objects at an infinite distance are practically parallel; that an eye of the right length does not need to exercise muscular strength in order to unite these parallel rays so that they make an exact focus upon the layer of rods and cones of the retina, where the image is received.

You will also remember that there is a ciliary muscle, represented in this diagram, which acts in a certain way upon the capsule of the lens so as to allow it to become thicker. Objects situated at a distance from the eye of less than twenty feet emit divergent rays. These are the two rays of light we find in nature. Those coming from an infinite distance are practically parallel, those from a point near at hand are divergent. The rays of light which come from an illuminated landscape one-fourth or one-half a mile distant or one hundred feet or twenty feet away are practically parallel. The rays which come from a book read at the ordinary distance at which it is held from the face, or at any distance less than twenty feet, are divergent. These are the *only* rays which nature exhibits. We may have convergent rays by the aid of lenses. This child has been receiving parallel rays, which came from illuminated objects situated twenty feet distant from her eyes, and she has been able to read the letters in the bottom line. Are you ready to assume, now, because she has done that, that her eyes are of the

right length? You cannot safely assume that, because she may have been making an effort, such as the properly shaped eye does not make, in order that vision may be clear. In other words, she may have been using her ciliary muscle in order to thicken this lens and increase the refractive power of the eye. By that effort she may have been able to see $\frac{3}{8}$, and yet her eyeball may have been too short from before backward. Yet she by muscular effort may have made it practically longer.

As general practitioners we can now exclude short-sightedness, or myopia; and we can also exclude amblyopia, because her vision is $\frac{3}{8}$; she is certainly not presbyopic, for that is a disease of accommodation occurring from lapse of years. What kind of defective sight has she? We have reached, by exclusion, the diagnosis that she is in one of two conditions: 1, that her eyeballs are exactly of the right length, that she is emmetropic; or 2, that her eyeballs are too short, and by using her ciliary muscle she has been making her lenses long enough to enable her to focus these parallel rays. She may have latent hypermetropia. How am I to find out which one of these two conditions is present? We have a test which will enable us to answer that question with certainty. Here is a case of glasses which costs some ten or twelve dollars. It contains glasses for answering the question that has arisen concerning the sight of this girl. By means of the test-types and these glasses you can answer the question. Is she hypermetropic, that is, are her eyeballs too short, and is she obliged to constantly use her ciliary muscles in order to see clearly, even at a distance; or is she emmetropic, that is, has normal eyes, and does the asthenopia or weak sight depend upon some general condition of the system, such as anæmia, want of general muscular tone, or the like?

If I put a convex glass over the eyes of a person whose vision is accurate and normal, who has never suffered from weak sight, a glass which increases the refraction of the eye, it has the same effect as if the eye is entered and the lens thickened. The eye will not then be adapted for parallel rays and a "blur" will occur, clearness of vision will be interfered with. We know that fact practically, and we explain it by saying that the normal eye is in a state of rest while looking at an infinite distance, and does not need any assistance to the ciliary muscle. If we put a glass upon it which makes the eye slightly too long, slightly myopic, there will be a blur, because the image will not be accurately focussed.

Let us apply our test. I will first use this lens, No. 60, a glass of sixty inches focal distance.

It will make a difference in vision at once when placed before the normal eye. It may or may not make a difference in the vision of our patient. [Glass applied and patient asked to read.] She says that the bottom line of the test-type is clearer than without this glass. That result might be a delusion, as perhaps she may have obtained the idea from what has been said or from the mere fact of a glass being put upon the eye, that we expect her to see better; but we will go on and apply a glass that has a 48-inch focal distance.

Some authorities say that a hypermetropia of $\frac{1}{8}$ is not to be regarded. Practically I agree with that statement, and also that if we find hypermetropia of $\frac{1}{8}$ it is not always to be regarded, because, as has been shown by examination of eyes under atropia by myself, and the eyes of young children as examined by Dr. Ely, most people are hypermetropic. Donders stated that fact a long time ago, although he did not bring forth the special proof. You may accept it as a fact that the larger proportion of eyes are slightly hypermetropic, and there are more eyes hypermetropic than myopic.

But when a glass of 48-inch focal distance is required for distinct distant vision, or when it is tolerated, and the sight is just as good with it as without, we may fairly assume that the patient who thus requires or tolerates a glass is hypermetropic, for when the ciliary muscle is put at rest by atropia it will be found that there is a latent

hypermetropia added to that found before this occurred. But there are some persons, as I have shown by experiment, who even when their ciliary muscles are set completely at rest by the instillation for some days of a four-grain solution of atropia, will not tolerate any glass, but reject every one, having clearer vision without it.

Now I will add this glass, having a 48-inch focal distance. She says at once that the letters are not so clear as without the glass.

I will now have her keep looking at the test-types while I arrange another glass, and I do that in order that she will keep up the exercise of the ciliary muscle. I now put upon the eyes No. 40, and she says that she sees clearer than with either of the glasses tried. I will not consume time by extending the examination further, for we have demonstrated that she has hypermetropia, her eyeballs are too short, and although she can see $\frac{3}{8}$, she is using unnatural muscular force in order to do it. We will therefore order for her a pair of convex glasses with 40-inch focal distance and see what the effect will be upon the symptoms of which she complains.

It is probable that she will soon allow her ciliary muscle to give up its excessive work, and let the lens in front of the eye serve to thicken the lens within it. This rest to the muscle may, and probably will, relieve the symptom of pain, fatigue, etc., caused by its undue or excessive action.

The case is one of *facultative* hypermetropia. It is not *latent*, for then the patient would have rejected all glasses until atropia or a drug with similar effect had paralyzed the ciliary muscle. Her vision is $\frac{3}{8}$ *with* and *without* convex glasses. It is not *manifest* hypermetropia. Then the patient would have seen well at a distance only *with* convex glasses.

You have spent twenty-five cents for test types and twelve dollars for a case of glasses. You have shown that these troublesome symptoms, blurring of the sight, watering, burning of the eyes, depend in this case not upon straining to see through a cloudy medium (an opaque cornea or a cataractous lens), or a vain effort to get a sharp image on an inflamed or hemorrhagic retina, but upon undue exercise of an overweighted ciliary muscle, and you have made a diagnosis in an obscure case.

I will finish the lecture by presenting a case which furnishes a striking contrast with the one which we have just examined. This is a case which the general practitioner could not make out, unless he had had some special training, and I put it in contrast with the other in order to show you where is *the dividing line between the knowledge that may be expected from a general practitioner, and that demanded from one who gives special and perhaps exclusive attention to diseases of the eye.*

This young man has had inflammation of the right eye, which has practically destroyed it so far as vision is concerned. There is general staphyloma of the cornea and only that perception of light which oculists call quantitative. The left eye has not been injured, but the sight is weak, and he is naturally anxious to know whether it has undergone any change in consequence of sympathetic irritation or inflammation. We look at it, and see that it does not water, it is free from redness, the pupil moves well, but he has the symptoms of asthenopia enumerated in connection with the other case. He can read next to the bottom line; that is, his vision is $\frac{3}{8}$. I take up my general practitioner's case of convex and concave glasses and am not able to make him see $\frac{3}{8}$, and I begin to be alarmed. I say that he has lessened sight in that eye with a bad condition of the fellow eye, and I send him off to a specialist, and that is well enough.

Now I will put a convex cylindrical glass before his eye, a glass of which the general practitioner is not bound to know anything, except as a matter of general professional information. I take one of 48-inch focal distance—I have already reached this by a series of

experiments with the patient—and I find that his vision reaches $\frac{2}{3}$. This is a cylindrical glass, the one used in correcting astigmatism.

The asthenopic symptoms do not depend upon the irritation of the other eye, but upon the same cause as that just given in the case of the little girl—undue action of the ciliary muscle in endeavoring to focus an image. But this eye, unlike that of the little patient, is too short in but one meridian (hypermetropic astigmatism). Her eye was too short in all meridians (hypermetropia). The latter condition is easily ascertained by a general practitioner educated in the last ten years. The former may properly be left for correction, if not for detection, to a specialist.

We can say, in this case, that there is no sympathetic irritation or inflammation. Sometimes people are supposed to have sympathetic irritation when they are merely affected with an error of the refraction of the eye. The latter fact is sometimes only discovered after a dangerous accident has occurred.

TUBERCULOSIS IN INFANTS.¹

By J. LEWIS SMITH, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

THESE specimens exhibit the lesions of acute miliary tuberculosis occurring in a child. The history of the case is as follows:

James —, aged ten months, was taken sick January 16, 1883. He was returned to the New York Foundling Asylum January 20th. He was apparently well-nourished and was wet-nursed. He had a severe cough, with dullness on percussion, and large and small râles in both lungs. The respiration was increased in frequency, and was shallow. Diagnosis, broncho-pneumonia. The child continued to grow weaker, the dullness became more and more marked, and he died at 4.15 A.M. January 24, 1883.

The autopsy was made by Dr. W. P. Northrup, pathologist. The body was well nourished.

Brain.—A few tubercles were found scattered over the surface in the pia mater; otherwise normal.

The *spinal cord* was normal.

The *lungs*, both external and cut surfaces, were thickly studded with large, well-defined tubercles. The bronchial glands were large and cheesy, and one contained a thick creamy fluid. The portions of lung-tissue between the tubercles were mostly consolidated, and presented the appearance known as "raspberry jam." There was one cheesy nodule, about the size of a hickory-nut, at the anterior edge of the right upper lobe.

The *heart* was normal.

The *liver* contained tubercles about half the size of those seen in the lungs.

The *spleen* was of normal size, but contained tubercles in abundance.

The *kidneys* showed five or six large tubercles in the cut surface.

The *stomach* was normal.

The *intestines*.—The mucous membrane of the small intestine was congested and showed occasional ulceration of the solitary follicles; some of the solitary follicles in the large intestine were also ulcerated. The ulcers were shallow, and had thickened edges.

The *mesenteric glands* were enlarged and cheesy.

Besides these specimens, I have others removed from the body of a phthisical child who died at the age of seventeen months. He had the following history:

Joseph —, a twin, aged seventeen months, was sent out to board in September, 1881. He was always a feeble child, and the record states that he suffered from cholera infantum in December, 1881. He returned to the asylum January 24, 1883, and died four hours afterward.

The autopsy was made by Dr. W. P. Northrup, pathologist. Marked emaciation. The brain was normal. There were cavities in the upper lobes of both lungs, containing thick, greenish-yellow fluid. The bronchial glands were enlarged and cheesy. A few small, transparent tubercles were seen on the surface of the lungs. The heart was normal. Small tubercles were scattered sparsely through the liver. The spleen, the kidneys, and the stomach were normal. The mesenteric glands were enlarged and cheesy. The small intestine showed ulceration of the lowest Peyer's patch, and occasionally ulceration of solitary glands. Similar ulcers were found in the large intestine.

Remarks.—Tuberculosis in young children is more common among the city poor than those are probably aware who observe diseases chiefly in the better walks of life. Two post-mortem examinations at the same time of tubercular children implies this frequency. In the etiology of tuberculosis in children two important factors occur. First, inheritance; secondly, the occurrence of caseous material in some part of the system. The child of a tubercular parent, as is well known, is much more liable to tubercles than is one of healthy parentage. The tendency to it appears to be greater when the mother is suffering from it than when the father is the invalid. If the mother have advanced consumption, her child is apt to begin to cough when a few weeks old, and sometimes when only a few days old, although it may have been born of full size and plump. As tuberculosis advances the more rapidly the younger the age, the child thus affected is apt to perish before the mother. Such cases have now and then occurred in my practice.

Much attention has recently been given to the theory of the infectiousness of tuberculosis—a theory that is gaining ground by observations which appear to substantiate it, and by the probable discovery of the tubercule bacillus by Koch. Certainly the fact that wives who are devoted to their consumptive husbands, sleeping by their sides, and perpetually inhaling their breath, now and then contract the disease—contract it apparently more frequently than those who are not so exposed—lends support to this theory. It seems probable that tubercular particles, to which, perhaps, bacilli are attached, exhaled from tubercular lungs, and lodging in the lungs of the exposed individual, may excite by their irritation the cell-proliferation, which produces the tubercular neoplasm. If this theory be true, as seems probable, we would expect that infants who are held in the laps of diseased mothers or nurses, and whose lungs are delicate and susceptible to morbid influences, would be especially liable to be attacked, and the journals have recently published the case of a midwife in a European town who had confirmed tuberculosis, and had been in the habit of blowing into the mouths of new-born infants under her care. A considerable number of these infants perished with tuberculosis, while those in the practice of another midwife who was healthy escaped.

Another, and in my opinion the common mode in which tuberculosis arises in children, is from cheesy foci. The child takes inflammation from some cause, perhaps from exposure to cold, and on account of feebleness of system or a pronounced cachexia, the inflammatory products do not resolve. Remaining in the system, they undergo caseous degeneration, and caseous material furnishes the conditions, as is well known, in which the tubercular neoplasm often originates. Detached caseous particles lodged in the tissues excite the cell-proliferation, which produces the tubercle. Hence in post-mortem examinations we so often find a cluster of tubercles around caseous matter.

The two sets of specimens before us show the ordinary anatomical characters of tuberculosis in infancy.

We know the rule in the adult, that tubercular matter first appears at the summit of the lung and extends downward, the amount of tubercle being greater at the apex than elsewhere and at a more advanced stage. At

¹ Presented at a Stated Meeting of the New York Pathological Society, January 24, 1883.

the apex we find softened tubercles, and sometimes tubercular cavities, while in the central and lower part of the lungs we find either no tubercles or tubercles disseminated and recent. In the infant, on the other hand, miliary tubercles are disseminated throughout the lungs, nearly the same in size and appearance in every part, with surrounding healthy lung-tissue. Hence the difficulty in making a diagnosis except at an advanced stage, for we do not obtain dulness on percussing the chest, until at a late period, when inflammations have arisen to consolidate the lung at some point, and on auscultation we only observe a rough or rude respiration. In the tubercular infant, as a rule, the bronchial glands are enlarged and cheesy, with softening of some of them in their interior. The so-called bronchial phthisis plays an important rôle in many cases, producing various severe symptoms. Hyperplastic or caseous bronchial glands by pressure on a bronchus, cause narrowing of its lumen, and consequently more or less obstruction to the respiration; or by ulceration and discharge of caseous and softened gland substance into a bronchus, or into the lower end of the trachea, it produces a troublesome irritative cough. These glands sometimes also produce distressing, even dangerous symptoms, by pressure on important nerves, as the laryngeal, or important veins, as the innominate. In some cases which I have observed, the return circulation from the brain has been so obstructed from this cause as to produce dangerous cerebral symptoms. Extreme passive congestion occurred in the intracranial veins and sinuses from this cause.

These specimens also show another well-known fact in reference to the tuberculosis of early life, to wit: the tendency to generalization of the tubercles. They appear in the pia-mater, especially at the base of the brain, where they often give rise to tubercular meningitis. In one of the specimens before us tubercles were present in this location, but they had apparently produced no symptoms. Miliary tubercles appear almost as frequently in the spleen as in the lungs, and in as great number relatively to the size of the organ. They are found less frequently upon the surface of the liver, and less frequently still upon the surface of the kidneys. As in the cavity of the chest, miliary tubercles often occur in the connective tissue under the pleura, distinctly seen through this membrane, and raising it slightly, so that they occur under the peritoneum in any part of its extent, parietal, visceral, or omental, where they frequently produce localized peritonitis. They occur, also, not infrequently in the mucous membrane of the intestines, causing ulceration and a troublesome diarrhoea. Ordinarily, also, the mesenteric glands undergo great enlargement and caseous degeneration like the bronchial, but they are not so frequently softened.

The tubercles being thus widely disseminated in the system of the infant do not ordinarily give rise to any prominent local symptoms till they produce inflammation around them. Hence the difficulty of making a positive diagnosis at an early stage. We infer the presence of tubercles from the general condition, from the wasting, poor appetite, loss of strength, and the cough, but cannot say positively, as in the adult, that tuberculosis is present until the disease is pretty well advanced. The sputum is scanty, and is swallowed, hæmoptysis does not occur, but by and by we observe dulness on percussion over some part of the chest, due to pneumonic solidification, excited by tubercles, and this persists, for the inflammation kept up by such a cause does not resolve. Whenever the symptoms due to tubercular meningitis or bronchial phthisis arise, the diagnosis is of course easy.

Whenever, therefore, I am called to a young child with a chronic cough and wasting, I do not wait for a more accurate diagnosis, but if there be no diarrhoea to contra-indicate it, prescribe cod-liver oil with the hypophosphites, frequently adding the syrup of the iodide of iron, since the strumous cachexia is so apt to be present, with probably caseous substance, in some part. Such

a case requires the utmost attention to the hygienic management, pure air, nutritious, and easily digested diet, into which milk enters largely, the juice of meat or meat-broths, prepared at a temperature of 100°, so as not to coagulate the albumen. A favorite prescription in two of the asylums of this city for these infants with chronic cough and wasting, whether or not tuberculosis be diagnosed, is the following, to be taken between the doses of cod-liver oil:

R. Ammon. carbonat.,
Ferri et ammon. citrat. āā. gr. xxiv.
Syrupi simplici ʒ iij.
M.

Dose, one teaspoonful every two or three hours to a child of one year.

WHAT IS THE RATIONALE OF TRACTION AND COUNTER-TRACTION IN THE TREATMENT OF HIP DISEASE?

By A. B. JUDSON, M.D.,

ORTHOPEDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL.

As suggested by Dr. L. M. Yale,¹ the word traction should be used instead of extension, when reference is made to the common method of applying mechanical treatment in hip disease. Whatever form of apparatus is used, the object sought is traction. This cannot be secured, however, in any case except by the simultaneous development of counter-traction. If the extension and counter-extension (tractive and counter-tractive) apparatus is used, counter-traction is made against the inferior surfaces of the os innominatum. If the weight and pulley are used, it is found in the friction which the body makes with the surface on which it lies, and partly in the weight of the body if the limb is elevated. If the patient is standing, the affected limb being pendent, and its weight tractive, then counter-traction is found in the pressure made by the head of the sound femur on the floor of its acetabulum. Manually, traction may be made on the condyles of the femur and counter-traction on the prominences of the pelvis, and it is conceivable that in certain cases favorable to the experiment, the contracted muscles may be thus opposed or "counter-acted" while passive motions of the joint are made.

The reasons which lead to a substitution of the word traction for extension also lead to the use of the expression traction and counter-traction. This term will therefore be employed in the present paper, which is to be a brief inquiry into the validity of some of the accepted theories offered in explanation of the efficacy of this form of treatment.

When we view the application of traction to a case of hip disease, an obvious incident is the apparent drawing away of the thigh from the trunk. The inference has been made that the usefulness of the application depends on the separation of the head of the femur from the floor of the acetabulum. It is an interesting question whether this separation can be affected in the cadaver. The experiments of Barwell² and Morosoff³ sustain the negative, and those of Koenig and Armand⁴ the affirmative. It is probable that both sides are partly right, and that the facts have been indicated by Dr. Edward H. Brad-

¹ Dr. Yale writes: "The word extension is objectionable because of its obscurity, since it is used as the opposite of flexion." (MEDICAL RECORD, January 12, 1878, p. 27.) The point thus made had been aptly illustrated in the discussion which took place in the New York Academy of Medicine (Am. Med. Times, April 27, 1861, p. 279), when Dr. Bauer was credited with the very early use of extension (traction) in hip disease, although his method really consisted in the reduction of flexion followed by fixation. (N. Y. Journal of Medicine, September, 1853, p. 173, the method of Bonnet and of Hilton.)

² Diseases of the Joints, pp. 336-342, London, 1861. American Edition, 1881, pp. 16-18.

³ Quoted by Charles Monod, Arch. Gén. de Médecine, p. 718, June, 1878.

⁴ Jules Armand: Thèse de Paris, pp. 30, 31, 33, 34, 1878.

ford,¹ whose experiments show that in some conditions of development, and perhaps of disease, this separation is possible with ordinary effort, while in other conditions it cannot be effected by extraordinary force.

The question of the therapeutic value of attempting to separate these surfaces has also given rise to varying opinions, some writers believing that it is an important part of mechanical treatment. Dr. L. A. Savre is reported as holding this opinion,² but I do not find it expressed in any of his valuable writings on this subject, and the weight of contemporary authority is decidedly opposed to such a view, if we may judge from the following quotations: "It is not possible for the two articular surfaces to be directly separated by an extension so insignificant" (Bauer).³ "I do not believe it (the drawing out of the head of the bone) occurs, or ought to occur, nor do I believe it would be anything but harmful if it did occur" (C. Fayette Taylor).⁴ "This separation is scarcely possible under any amount of force likely to be employed by a surgeon" (Yale).⁵ "I do not believe it possible, by any amount of extension that can be applied, to separate the inflamed and swollen interior surfaces of the joint" (Hutchison).⁶ The united opinion of these authorities is an assurance that separation of the articular surfaces is not an adequate explanation of the efficacy of traction and counter-traction.

Fixing our attention still further on traction as applied to a case of hip disease, there is, in addition to an apparent drawing away of the limb from the trunk, an apparent antagonism between two forces, that of reflex muscular action and that of traction. There is thus produced an apparent counteraction of the muscles surrounding the joint, and the inference has been made that upon this depends the efficacy of traction and counter-traction. I believe, however, that their usefulness is entirely independent of the alleged counteraction of the muscles.⁷ While taking this ground I retain the highest possible appreciation of this mode of treatment, and find a satisfactory explanation on other grounds. Leaving to another occasion the consideration of the question whether "a fractional degree of fixation," such as is secured by traction and counter-traction is not the true explanation, it will be sufficient in this paper to critically consider the statement that traction and counter-traction owe their usefulness to the counteraction of the muscles.

That this opinion is widely entertained is evident from the following quotations from writers of note, American and foreign, who have considered this method from a practical point of view. "It is obviously of importance in treatment (1) to keep the surfaces at all times from contact, and (2) to control the muscles." "This constant contraction of muscles passing over a joint should always be counteracted." "The India-rubber spring counteracts that force which presses the bones too violently together." "To overcome the injurious pressure from irritated muscles is imperative." "The object of extension is to overcome reflex muscular action." "The object of such appliances is merely to

relieve the joint from pressure, by permanently extending the morbidly contracted muscles."

A proposition drawn from the above expressions, no two of which are from the same authority, may be worded as follows: Traction and counter-traction are useful in hip disease because of their power to counteract the muscles which are injuriously contracting around the joint. If it can be proved that they have not this power, or if undue importance has been ascribed to the action of the muscles in question, then the reason of the efficacy of this form of treatment must be sought elsewhere. Although I believe that the muscles cannot be thus counteracted to any practical degree, it is impossible to give a demonstration from the nature of the case. All that can be done will be to present certain reasons for disbelief, leaving the question to the judgment of the reader.

There should be no obscurity in regard to the meaning of the term "to counteract the muscles." If the joint were fixed the muscles would in a certain sense be counteracted, because they would be prevented from action. But this is evidently not the meaning of the term. Nor does it apply to the effect of extension (the opposite of flexion), which would indeed counteract the flexor muscles, or to the effect of flexion, which would counteract the extensors. The term is evidently used with reference to all the muscles surrounding the joint, and it signifies to make traction on them in such a way as to prevent their contraction (or at least to obviate its pressure effects) by the direct application of a force acting in an opposite direction.

It is evident that a contracting muscle can be counteracted only when traction is made on the bone in which it is inserted. In the case of the hip-joint it is necessary to obtain a secure hold of the femur, and a little consideration will show that the ordinary method of grasping the femur by adhesive plasters applied to the skin is very imperfect. If our adhesive plasters could be applied directly to the bone, or if it were admissible to use a device like Malgaigne's hooks for the treatment of fracture of the patella, we might perhaps hope to make such traction on the bone as to counteract the muscles. The shaft of the femur may be said to occupy the middle of a cylinder of elastic integument, the space around it being filled with a jelly-like mass, composed mainly of relaxed muscular fibre and loose connective tissue. It is not denied that a slight amount of traction is thus exerted on the femur, but it is unreasonable to suppose that in circumstances so extremely unfavorable it is strong enough or steady enough to counteract the muscles which directly move the joint.¹ If the great muscular masses of the thigh and hip were in a state of rigid contraction the case would perhaps be different, but these muscles are, with few exceptions, in a relaxed condition in acute disease. In the thigh the adductors are probably the only muscles which are found in sustained contraction. The sartorius, gracilis, quadriceps extensor, the three hamstring muscles, and the tensor vaginae femoris are found (in acute disease) relaxed and atrophied. The reason for this exceptional condition of the adductors is perhaps to be found in the fact that they alone of all the muscles thus far enumerated have their origin in one osseous member of the joint and their insertion in the other, an arrangement which may make them more liable to reflex action, the result of *ostitis* near the joint. The *psaos magnus* has its origin above the *os innominatum*. The only muscles, then, which move the joint and have their origin and insertion immediately above and below it, besides the adductors, are the *iliacus*,

⁶ J. C. Hutchison: Contributions to Orthopedic Surgery, p. 9, New York, 1880. Mr. Howard Marsh believes that separation is impracticable (British Medical Journal, p. 99, July 28, 1877).

⁷ Because reflex muscular action—"vigilance musculaire" *Verneuil*. "If handled a little roughly, all the muscles will be upon their guard" *Davis*, American Medical Monthly, p. 323, November, 1862—is an important clinical feature and of great assistance in diagnosis, it does not follow that it is the chief element in the pathology and the point against which our local therapeutics are to be directed. There are occasions in practice when direct counteraction of muscular fibre is feasible and important, as in the cramps of the extremities in cholera and the nocturnal cramps of the sural muscles. In the treatment of stumps immediately after amputation, painful twittings may be prevented by traction (R. F. Weir, MEDICAL RECORD, p. 51, April 1, 1867). In Buck's extension for the treatment of fractures traction is believed to be useful by directly controlling the spasmodic twittings of the muscles (*ibid.*, p. 50). After excision of the hip the muscles may doubtless be contracted by a tractive force. But all these cases are so radically different from acute hip disease that an argument cannot be drawn from them. After excision or fracture the muscles are in a position peculiarly suggestive of the propriety of traction, because their points of origin are abnormally approximated to each other.

⁸ H. O. Thomas: Diseases of the Hip, Knee, and Ankle Joints, p. 10, Laverpool, 1875.

¹ Mr. Howard Marsh says: "I suppose the greatest amount to which the surface of the head of the femur can be separated from that of the acetabulum cannot be more than about the tenth of an inch. And it is very difficult to preserve efficient extension and counter-extension within this range; for the parts cannot be acted upon as if they were parallel metal plates to be adjusted by a screw; they must be controlled through the agency of perineal bands and strapping fixed upon the skin, and all these are apt to give when they are subjected to constant traction; and if they yield, though it be but slightly, they soon, in the aggregate, lose this tenth of an inch of extension which they should maintain, and then the articular surfaces come again into firm contact" (British Medical Journal, p. 99, July 28, 1877).

pectineus, glutei, gemelli, obturators, and quadratus femoris. The glutei are, as a rule, relaxed and atrophied. The gemelli, obturators, and quadratus femoris are simple rotators, acting only in horizontal directions. By this process of exclusion we have left as muscles liable to sustained contraction and proper subjects for counteraction the iliacus, the pectineus, and the adductors. Considering the secondary position of these muscles, when compared with the immense muscular masses of this region, it does not appear that counteraction is imperatively demanded for the protection of the joint, even if the mechanical difficulties above pointed out did not exist.¹

It is difficult to explain the efficacy of traction in hip disease on these grounds, while an easy and reasonable explanation is found in the opinion of M. Verneuil,² that fixation is of prime importance, joined with a recognition of the fact that traction and counter-traction furnish the best solution of the difficult problem of the fixation of the hip-joint.

Before concluding, however, it is necessary to review two theories which have been advanced for the purpose of explaining more fully how the alleged counteraction of the muscles promotes recovery.

The first was proposed by Dr. Henry G. Davis, who believed that the muscles could be counteracted by an apparatus which should at the same time allow the joint to perform its normal motions. He wrote: "I can but consider it highly beneficial to keep up motion of the joint, yet not allow of friction upon the diseased surfaces."³ This idea has been adopted by a number of eminent writers. One of them who declares that "motion is just as essential to a joint as light is to the eye,"⁴ advocates a "plan by which extension could be maintained that would remove pressure from the acetabulum and the head of the femur, and at the same time permit motion of the joint." Another has devised a combination of a plaster-of-Paris jacket with a hip splint, by which he claims that "extension and counter-extension and mobility of the affected limb are made feasible." Another has devised a splint in which "the movements of every joint of the limb is most perfectly secured; that at the hip especially not being in the least interfered with by the counter-extending force." Still another form of apparatus secures "mobility of the joint with extension," and a recent most instructive writer frankly admits that "up to the present day (1882) no effectual appliance to secure these results (motion and avoidance of articular pressure) had been afforded." The device which he advocates, although very ingenious, has not as yet perhaps been sufficiently tested by time to prove its superiority.

The idea entertained by these authorities is that the muscles can be counteracted by an apparatus which shall permit the ordinary motions of the joint. There are great mechanical difficulties in the way of the practical application of this idea. If traction and counter-traction are applied in the line of the thigh and the trunk, it is difficult to conceive that the same amount of force can be maintained through all the variations of flexion, extension, adduction, and abduction.⁵ The difficulty depends partly on the irregular shape of the inferior surface of the bony prominence made up by the body of the ischium and the rami of the ischium and pubes. As motion of the limb is made in different directions, different facets of this prominence, more or less removed from the lower end of the femur, are successively presented to the pressure of the counter-tractive part of the apparatus. If the facet

presented is prominent, traction will be more severe, if depressed, less severe. And even if we imagine the bony surface reduced to a mathematical point, presenting the same resistance to counter-traction from whatever direction it comes, there is a further difficulty in the fact that the point of counter-traction (ischiatric tuberosity) is on a lower level than the point of motion (acetabulum), the effect of which arrangement is that motion will make a change in the distance between the point of counter-traction and the point of traction (lower end of femur) with, of course, a change in the degree of traction. To prevent these variations it is necessary to make the point of counter-traction identical with that of motion, and on reflection it will be found that in this way alone, which is of course impracticable, can mobility be maintained with equable traction.

It has been supposed that the use of India rubber would facilitate the practical development of this idea. Dr. Davis himself, in 1860, described an ingenious apparatus partly constructed of this material, but this device failed to secure general adoption, and none of its successors has as yet proven its value.⁶

It is, indeed, desirable to adopt some theory in accordance with which traction and counter-traction may be transferred from empirical to rational medicine, but it surely is not necessary to adopt an explanation which is burdened with so many mechanical impossibilities.

The other theory also owes its origin to the fertile and ingenious mind of Dr. Davis.⁷ He formulated it in 1860, as follows: "When I speak of extension I do not apply the term to confining the limb in a given position, but to the process by which the soft parts are kept continually upon the stretch, whether by means of a weight or some elastic material, the result of which process upon the muscular fibre is to weary it and thus put it at rest."⁸ This idea has been entertained by a number of writers, American and foreign, from whom the following quotations are made: "It (India rubber) appears, by its unvarying, constant, and yet not unyielding power, to tire out the muscles." "By this force (continuous extension) the muscles are tired out and soon made to capitulate." "We must carry extension until the muscles relax, and then we must maintain the extension until they lose their irritability and the inflammation in the joint has been given time to become retrogressive." "The object of continued extension is to paralyze the muscles." "When the muscular contractions are completely overcome, and the muscles are thoroughly tired out, but little extension is needed." "The object of extension is not, as generally supposed, to separate articular surfaces, but to overcome reflex muscular contraction, and by relaxing the muscular rigidity to prevent undue pressure of inflamed articular surfaces." "Forcible traction being applied in the axis of the thigh, the muscles are fatigued and overcome and rendered incapable of contraction." "If prolonged and powerful traction be applied to a muscle, it will, after resisting for a time, at length yield and fall into relaxation." "We must overcome the contractility of the muscles governing the joint."

The idea contained in these quotations, no two of which are from the same writer, is that traction and counter-traction are curative because they deprive the muscles of their contractility. Muscular fibre may lose

¹ That the pathological facts do not call for the counteraction of the muscles in hip disease has been shown in a preceding article. See N. Y. Medical Journal, pp. 1-17, July, 1882.

² Verneuil teaches: 1, that prolonged fixation is powerless alone to produce ankylosis; 2, that the best way to prevent ankylosis is to combat inflammation; and 3, that fixation of a diseased joint is an antiphlogistic of the first importance (Bull. et Mém. de la Soc. de Chir. de Paris, pp. 510, 511, 1879).

³ New York Journal of Medicine, p. 420, November, 1859.

⁴ This proposition was questioned by a distinguished opponent, who said: "Light is for the eye in a healthy state, but in disease light should be excluded" (American Medical Times, p. 311, May 11, 1861).

⁵ Mr. Marsh says: "If the perineal band be adjusted when the limb is extended, it will become loose when the limb is flexed" (loc. cit.).

⁶ Dr. Davis, who employed an elastic perineal strap, described his invention as follows: "Quite at the top and inside of the splint is an eye, through which runs the catgut attached to the two ends of a perineal or extending band, and forms part of it when the whole is applied to the patient: the catgut, passing through this eye unconfined, allows the upper portion of the splint to traverse back and forth without disturbing the perineal band. All that portion of the splint that passes above the hip-joint has a motion of which the joint is the centre. By this management, allowing the catgut to traverse in the eye of the splint, the perineal band is not disturbed by any motions of the limb, and all irritation from motion is avoided" (American Medical Monthly, p. 264, April, 1860).

⁷ Referring to "artificial muscles," Dr. Davis in 1856 wrote that "when contracted muscle is to be overcome, it (India rubber) stealthily wearies it until it silently comes off conqueror" (Am. Med. Monthly, p. 330, May, 1856). In 1859 he related a case of hip disease in which, on the application of continued traction, the muscles became "worn," so as to allow the head of the bone to come down upon the inferior portion of the acetabulum" (N. Y. Journal of Med., p. 418, November, 1859).

⁸ Am. Med. Times, p. 149, September 1, 1860.

its contractility from rupture or from degeneration, but that it surrenders this high endowment to the application of traction is, to say the very least, extremely questionable. If an elastic force be used the muscles to which it is applied would probably increase in size and vigor from the exercise. If an unyielding force be used we have already seen how great are the mechanical difficulties to be overcome. But if it were possible to grasp the femur and maintain unyielding traction, the amount of stretching is necessarily limited by the ligaments of the joint, and furthermore is extremely minute when compared with the elongation to which the muscles are accustomed in the ordinary motions of the joint. When, for instance, the thigh is extended on the trunk the flexors are of course relaxed and lengthened, and this normal lengthening is so great that it is unreasonable to suppose that the minute degree of stretching which traction and counter-traction produce can determine any important change in the qualities of the muscular fibre.¹

It thus appears that this theory also contains points of fatal weakness.

Which of these essentially different theories shall we adopt? Shall we say that the hip splint secures mobility with traction or deprives the muscles of their contractility? Authorities are clearly divided. The fact that there are two current explanations calls for caution before the adoption of either and suggests the possibility that neither is the true one. And if this possibility were to become a certainty, and if fixation were recognized as the key to the efficacy of traction and counter-traction, these conditions would not lessen the value of the hip-splint or materially diminish the credit of those who have illustrated American surgery by its invention and use.

ELECTROLYSIS IN THE TREATMENT OF ORGANIC STRICTURE OF THE URETHRA.

By J. H. GLASS, M.D.,

UTICA, N. Y.

THE desideratum in the treatment of organic stricture of the urethra has been an operation that would effect a radical cure, thus avoiding to the patient the disagreeable necessity of introducing a sound at certain intervals (perhaps for a lifetime), as is now demanded by the recognized operations. Although my individual experience in the treatment of these cases by electrolysis is limited, I have uniformly obtained results so flattering that in defence of the operation I take the liberty to present an abstract of them.

The somewhat meagre literature of this subject is so unsatisfactory and conflicting that it seems to me to be the duty of those who may have applied this method of treatment to offer in evidence their experience. Should this be done, the operation would soon be accorded the position it deserves—either that of more general recognition by the profession (which I believe it will have) or a more general condemnation. The great variance of opinion on the value of this operation is well illustrated by two articles, one appearing in the *New York Medical Journal* for December, 1871, by Professor E. L. Keyes, the other in the *Archives of Electrology and Neurology*, for May, 1874, by Dr. Robert Newman. Respectively one reports uniform bad results from its use, and unqualifiedly condemns; while the other reports uniform good results and most heartily commends the operation. As the opinions of these two distinguished men may be said to be representative of the opinions of most others who do, or do not favor the operation, perhaps a cursory review of them would not be out of place. Dr. Keyes says: "I operated upon ten cases, and from that amount of ex-

perience, cannot but condemn the operation *in toto*. The operation is disagreeable, often very painful, the pain sometimes lasting several days, and vesical symptoms were always aggravated when they pre-existed." In all but one of Dr. Keyes' cases the patient is reported as having refused further operation or disappeared before observations were completed.

In the remaining case the treatment was abandoned. Granting that the operation is disagreeable and painful as conducted by him, is there not something of inconsistency in so summarily condemning the efficiency of the operation when viewed from a purely curative standpoint? To the use of potential currents, prolonged applications, and too short intervals between applications I think Dr. Keyes' failures may be fairly attributed. The distinctive feature of Dr. Newman's treatment, as compared with that of Dr. Keyes, is the use of *very mild* galvanic currents, "just perceptible to the patient." The current is passed but from three to five minutes. No force is used in the manipulation of the bougie and long intervals, two to four weeks, advised between applications. As with others, the negative pole is used for the insulated bougie, while the positive pole is applied to the thigh through the medium of a sponge. Dr. Newman reports over thirty cases, all of which resulted successfully. To the adoption in the main of his principles of treatment I ascribe the successful results obtained in the following cases. However, some allowance may be made for the fact that with one exception, my cases were uncomplicated and of large calibre.

CASE I.—C. W. D.—, aged twenty-six; single. First gonorrhœa at twenty-one; second and last attack contracted at about twenty-five, since when he has had a constant muco-purulent discharge. Otis bougie No. 12, American scale. (Here I may remark, to prevent repetition, that all measurements hereafter given in this report will conform to the American scale.)

January 5, 1880.—No. 13 held lightly against the stricture and current from ten cells passed for five minutes, when the sound passed on into the bladder.

January 19th.—No. 13, after one minute's application, passed and was followed by No. 14, which also passed easily after three to five minutes.

February 10th.—No. 14 passed without grasping. No. 15 passed after five minutes' application.

March 6th.—Patient called to say that he had had no symptoms from his trouble for the past three weeks. On examination I can discover no induration, and as No. 15 passes without grasping, this number representing the maximum calibre of his urethra, he is discharged recovered.

CASE II.—B. S.—, aged eighteen; unmarried. Two gonorrhœas, the last six months since. This case, in all essentials being a duplicate of No. I., I will not further detail it, suffice it to say that the recovery was complete.

CASE III.—J. J. H.—, aged thirty-one; married. This case is of interest from the fact that the stricture developed from a bastard gonorrhœa, and could not have been induced by potential injections, as they were never used. While out on a duck-shooting excursion in the fall of 1879 was severely chilled. Took considerable diffusible stimulants. Coition with wife on his return (who had a leucorrhœa consequent upon an anteflexion of the uterus) was followed by a "bastard clap," which, as he modestly remained away from a physician, has continued to grow worse, until at this examination, February 1st, I find him with a resilient and irritable stricture which admits with considerable grasping No. 13. No. 14 passes under the effect of electrolysis in about six minutes, with some pain.

February 13th.—Nos. 14 and 15 pass after five minute intervals with inconsiderable pain.

March 7th.—No discharge. No. 16 passed under mild current from ten cells.

April 10th.—No. 16 Van Buren's sound passed with-

¹ Traction applied to the flexors by extension, as opposed to flexion, is not of course relied on to deprive the muscles of their contractility, because in this case there would be the obviously absurd application of traction to one set of muscles, the flexors, and relaxation to their opposites, the extensors.

out battery. No perceptible induration. Consequently discharged.

CASE IV.—W. L.—, aged nineteen; unmarried. Third gonorrhœa. Cannot explore urethra, as it is a case of congenital occlusion with hypospadias three-fourths of an inch posterior to the frænum. With a long, narrow, and straight bistoury, made an artificial urethra to admit a section of a No. 12 English catheter, which is fortified with a tin canula inside to prevent its collapse. This is kept *in situ* nearly two weeks, until February 21st, when I explore his urethra to find a tortuous stricture, about three-fourths of an inch long, occupying that portion of the urethra just anterior to the bulbo-membranous junction. No. 8 passes with considerable pain, also No. 9, after about ten minutes with rather strong current from twelve cells. Well-marked chill during the night, but no untoward symptoms after. On the fifth day a cast of the urethra one-half inch in length comes away.

March 5th.—No. 9 passed with some pain. Twelve cells.

March 24th.—Passed Nos. 9, 10, and 11 within fifteen minutes. Twelve cells. Considerable pain. Some febrile reaction during night and next day. Another small urethral cast comes away.

March 28th.—Some cystic irritability with consequent frequency and ardor in micturition. Under treatment these symptoms rapidly subside.

April 15th.—Passed without pain of note Nos. 11 and 12. Ten cells.

May 10th.—Passed easily Nos. 12 and 13.

June 3d.—Passed Nos. 13 and 14.

June 27th.—Passed Nos. 14 and 15. No pain.

July 15th.—Dolbeau's operation was performed for cure of the hypospadias. Result successful.

July 30th.—Slight narrowing of urethral calibre at point of last operation. Passed No. 15. Ten cells.

August 20th.—No. 15 Van Buren's sound passes easily without the aid of battery. Patient discharged.

CASE V.—P. H. M.—, aged thirty-five; married. Fell from hay-loft eight months since, striking the perineum on an inch board. Examination this day, April 1st, reveals an annular stricture of the membranous urethra, which will pass a No. 9 bulbous bougie, with current from ten cells. No. 10 passes after five minutes.

April 20th.—Nos. 10 and 11 pass without trouble or pain worthy of consideration.

May 12th.—Nos. 11 and 12 pass easily. Patient says he can now hold his water from three to five hours, and it comes away in a good stream. When commencing treatment was obliged to urinate frequently, proof positive that in this case, at least, vesical irritability was not aggravated by the treatment by electrolysis.

May 28th.—Pass easily Nos. 12 and 13. Patient declares himself cured.

June 20th.—Pass Nos. 13 and 14 with ease.

July 18th.—Pass No. 14 Van Buren sound without the aid of the battery. Patient discharged.

CASES VI. and VII.—April 16th.—Two young men, aged respectively twenty and twenty-one, both unmarried, came to me for treatment. I humored their request and examined and treated them together. Together I will report them also, as one will answer equally well for the other and some time will be saved. Both attended the same camp-meeting in the fall of 1879, and both, as they rather inelegantly but tersely expressed it, were "burnt" by the same woman. Both tried the abortive treatment for gonorrhœa and failed. Both, as examination proved, had a double linear stricture of the pendulous urethra, in each of which a No. 12 bougie was admitted. Passed with ten-cell current No. 13 on each.

May 1st.—D— and P— came together. Passed on each No. 14 with mild current of ten cells. No pain complained of by either.

May 20th.—D— and P— report decided improvement in their symptoms. Passed on each No. 15. Ten-cell current.

June 2d.—Pass on each, D— and P—, No. 15 Van Buren sound without the aid of battery. No induration discoverable in either case, and as this number represents the normal calibre of their respective urethras, both are discharged recovered.

CASE VIII.—May 30th.—F. E. S.—, aged fifty; married; wants to be relieved of his impotence, he says; gives history of gonorrhœa five years since. Has mucopurulent discharge, etc. Found stricture of No. 9 calibre at bulbo-membranous junction; passed No. 10 with mild current from ten cells; complains of some pain. After operation a considerable flow of muco-pus and cheesy matter occurred which had evidently been dammed back in the vicinity of the orifice—Cowper's duct—by the undisturbed stricture; advise abstinence from any attempt at sexual intercourse.

June 23d.—Nos. 11 and 12 passed without considerable pain within fifty minutes.

July 15th.—Patient reports a good degree of sexual vigor returned; pass Nos. 12 and 13 with ease.

August 6th.—Patient reports progress; pass Nos. 13 and 14.

September 1st.—Pass Nos. 14 and 15 with usual mild ten-cell current without trouble. No. 15 being the normal calibre of his urethra, nominally discharged him, highly gratified with his returned health and virility. Told him to come for final examination in course of five or six weeks.

CASE IX.—August 22d.—M. B.—, aged twenty-eight; married. Had first gonorrhœa five months since, which still continues to trouble him; meatus admits No. 9, freely cut this. Further examination reveals stricture of No. 12 calibre two inches posterior to the meatus; pass No. 13 with mild current from ten cells; no untoward symptoms.

September 19th.—Can detect very little thickening; pass No. 14; current as usual.

October 2d.—No thickening; pass No. 15 and discharge him.

It will be noticed that all of the above cases were discharged recovered from one year to eighteen months since. By recent communication I find that in no case has there been any return of stricture symptoms. This, I think, justifies me in the claim that a complete and radical recovery was effected in each case.

In view of these results, and the fact that of the more than fifty cases I have treated by other methods, mainly gradual dilatation, twenty-one per cent., owing to neglect of instruction given or other cause, have returned within six months for further advice. I deem the above nine cases treated by electrolysis a substantial argument in favor of more extensive employment of the operation in question.

A HISTORICAL CASE OF ACQUIRED AUTOMATISM.—The venerable pianist, Franz Liszt, says the *Times*, has ceased to play in public on account of the stiffness of his finger-joints. The fact recalls the method by which he used to keep his fingers supple, a method which is also an interesting illustration of acquired automatism. It was his custom for more than forty years to read a mass immediately upon rising in the morning, and when that duty was finished to seat himself at the piano. So seated, he placed on the rack in front of him, not a musical composition, but some new work of French or German literature, first being careful to mark the number of pages which he intended to read. Then for a long time, sometimes for two or three hours, he would continue to read his book and practice scales. On one occasion, being asked if the reading did not interfere with the playing or the playing with the reading, he replied: "Oh, no, the playing of the scales is entirely mechanical with me, and simply exercises the fingers; I give all my mind to the reading, very much as do our good ladies who knit stockings and read at the same time."

Progress of Medical Science.

SYPHILITIC REINOCULATION.—Dr. Scavenzio relates the case of a woman, thirty-five years of age, who was under treatment by the iodides for some of the tertiary manifestations. All at once she was seized with a feeling of general malaise, and in a short time presented a diffuse syphilitic roseola and sore throat. In seeking a cause for these new symptoms, Scavenzio ascertained that the woman had had an indurated ulcer at the entrance of the vagina, four months previously, which was followed by a non-suppurating inguinal adenitis. The iodides were stopped and injections of calomel given subcutaneously. Under this treatment the new symptoms promptly subsided. The author does not believe in an acquired immunity against syphilis. He is inclined to admit the possibility of auto-inoculation, which, he thinks, would explain the great irregularity in the course and duration of the disease, and also its liability to relapses.—*Lyon Medical*, March 25, 1883.

THE REPARATIVE PROCESS IN CARTILAGE.—Dr. Gies opened the knee-joint in young dogs under strict antiseptic precautions, and excised a piece of the articular cartilage, taking care not to wound the bone beneath. The operation was never followed by the slightest inflammatory reaction. After the animals were killed the wound in the cartilage was seen to be surrounded by an "atrophic zone," in which the cells were degenerated or had disappeared. Around this was a "proliferating zone," characterized by enlargement and segmentation of the cartilage cells and an increase in the number of nuclei. In no instance was there the least trace of a reparative process. Incised wounds of the cartilage, even after five months, showed no tendency to union. Here also, as in the case of actual loss of tissue, were seen the atrophic and hypertrophic zones parallel to the fissure. In a second series of experiments, the knife with which the cartilage was incised was previously dipped in a putrid infusion. The results now obtained were the same as those of other experimenters who operated without antiseptic precautions. Proliferations from the inflamed synovial membrane filled the wound in the cartilage with round and spindle cells. Presently cartilage cells appeared in the newly formed tissue, and in three months the wound was entirely filled with hyaline cartilage, so that scarcely any trace of the former injury could be discerned.—*Centralblatt für Chirurgie*, February 17, 1883.

REMOVAL OF WARTS BY CAUTERIZATION.—Dr. Cellier recommends the following treatment for warts in the *Journal de Médecine et de Chirurgie Pratiques* for March, 1883. The base of the wart is transfixed by an ordinary pin, care being taken not to pierce the healthy tissue beneath. Then, the skin being protected, the head of the pin is held in the flame of a candle. In a few minutes the wart becomes white and fissured, and comes away on the point of the pin. The procedure is said to be painless as well as bloodless. The curious assertion is made by Dr. Cellier that it is necessary to remove but one wart on the hand, and all the others (sometimes even a dozen or more) will disappear without treatment.

ARSENICAL PARALYSIS.—Dr. C. K. Mills relates a case of paralysis following arsenical poisoning in a young man twenty-four years of age. The patient was in good health prior to the time of eating the food which contained the poison. The first symptoms were repeated attacks of vomiting and a sense of great prostration. The bowels were confined. Six days after the arsenic had been taken a sensation of aching and numbness about the knees was complained of. This extended gradually toward the feet. Three days later the same sensations were experienced in the hands. Paralysis of the legs soon set in, and there was also some loss of power in the forearms. The patient's condition now remained station-

ary for two or three weeks, when he began to suffer great pain. The pains began in the knees and gradually invaded the legs and feet. Two days later the hands were affected in the same way. The following was his condition ten weeks after the poisoning: There was no brain symptoms and no disturbances of sight, hearing, taste, or smell; emaciation was marked; paralysis below the elbows was not complete, the extensors and supinators being most affected; there was somewhat less power in the right limb than in the left; the elbows were flexed at right angles and could not be wholly extended without causing pain in the flexor tendons; both legs were completely paralyzed below the knees; the knees were not flexed; the bowels were torpid, and for a few days there was a little dribbling of urine, but this soon passed away; farado-contractility was abolished in all muscles below the knees; above the knees the faradic reaction was greatly diminished, but not wholly absent; the muscles below the knees would not respond to weak galvanic currents; to medium currents they responded, but showed the reactions of degeneration. In the upper extremities farado-contractility was decreased, but not lost. To the galvanic current the reaction of degeneration was present, but not so decidedly as in the legs; the patellar reflex was abolished; the cremaster reflex was marked; irritation of the right lower extremity, as far down as the malleolus, caused retraction of the right testicle, and occasionally of both. Irritation of the left thigh and leg caused a less vigorous retraction of the left testicle, and occasionally, a moment later, slight retraction of the right testicle also. Irritation of one limb never caused retraction of the testicle on the opposite side only. The fingers and forearms were hyperæsthetic, but there was inability to distinguish between one and two points of the æsthesiometer. This condition was more marked in the feet and legs. Dr. Mills concludes from his analysis of this case that in arsenical paralysis we have to deal with a diffused myelitis, decided motor, trophic, and sensory bilateral phenomena being present.

IMMUNITY OF ANIMALS FROM SYPHILITIC INOCULATION.—Professor Neumann has made a number of attempts to inoculate animals with syphilis, but without success. The experiments were made with the greatest care, the virus being taken directly from the diseased person and introduced into the body of the animal. The animals experimented upon were kept under observation for a considerable period of time after the inoculation. In no case did any results obtain other than those which would naturally follow the introduction of an irritating material into the tissues. Nothing that bore any resemblance to a chancreous tumor was observed. The animals employed in these experiments were three apes, three rabbits, a horse, a hare, a white rat, a marten, and a cat. The total number of inoculations was fifty-four. Neumann concludes from these experiments that we must regard syphilis as distinctly a disease of man.—*Med. Central-Zeitung*, January 24, 1883.

OPERATIVE MEASURES IN ACUTE PERITONITIS.—Dr. Reibel relates the case of a child, eight years of age, suffering from acute idiopathic peritonitis. The disease having resisted all treatment and the child being apparently about to die, it was determined to open the abdomen with a view to removing the fluid and washing out the peritoneal cavity with a solution of carbolic acid. The meteorism was intense. No fluid was found in the abdominal cavity. In prolonging the incision, a loop of intestine was punctured, as evidenced by the escape of gas and intestinal fluid. The wound was washed with carbolic acid and covered with a layer of antiseptic cotton. The following day the little patient was nearly free from pain and was able to retain a little milk. The temperature had fallen from 104° to 101° and the tympanites was almost entirely relieved. The loop of intestine was adherent to the abdominal wall, and there had been no escape of fluid into the peritoneal cavity. The patient

made an excellent recovery. Inspired by his success in this instance, Dr. Reibel formulates the following rules for the surgical treatment of peritonitis in cases where life is threatened, by an extreme degree of tympanites: 1. Open the abdominal wall by an incision about an inch in length. 2. If adhesions have formed between the two layers of the peritoneum, make a little puncture in the presenting loop of intestine. 3. If there are no adhesions, cover the wound with a carbolized compress and wait a few hours until adhesions form, before opening the gut. 4. In the latter case, if the meteorism be urgent, a few punctures may be made with a fine trochar at once. The author does not regard the puncture of the intestine through the abdominal wall, as ordinarily practised, as of much utility. He thinks that the intestinal walls have lost their elasticity through overstretching and cannot expel the gas through a fine canula.—*Journal de Médecine de Paris*, February 17, 1883.

LIPOMA OF TRAUMATIC ORIGIN.—The following case is related by Dr. Kölliker in the *Centralblatt für Chirurgie* of March 17, 1883: A man was struck upon the left shoulder by a brick falling from a considerable height. When seen a few hours later, there was a tumor of about the size of a fist, formed of extravasated blood, over the outer third of the clavicle. This was reabsorbed in about six weeks. Three weeks later the patient presented himself again on account of a lipoma, which was growing rapidly, in the exact location of the previous ecchymosis. The tumor was removed shortly afterward and measured one inch in height by two and one-half inches in width. Kölliker thinks that possibly there may have been a small lipoma in this situation previous to the injury, though the patient denied positively ever having himself noticed a tumor there.

FATAL PURPURA HEMORRHAGICA.—Dr. Rongon relates the following case in *L'Union Médicale*, No. 17, 1883. A naval officer, sixty-four years of age, had suffered for several years with glycosuria in a mild degree. In the summer of 1882 he received a severe shock in learning of the sudden death of his daughter. Other troubles weighed upon his mind, and he became very despondent. Soon afterward he was seized with a profuse hæmaturia. This was followed by a deep hemorrhage in the scapular region. Purpuric spots made their appearance upon the abdomen and thighs. A few days later a sudden increase in volume of the right lower extremity was observed by the medical attendant, the left limb remaining of normal size. This was supposed to be due to hemorrhage, and the supposition was confirmed the following day by the discoloration of the skin. Hæmaturia and extravasations in various parts of the body continued until the death of the patient in syncope, thirty-seven days after the first symptoms had manifested themselves.

COLD ABSCESS OF THE TONGUE.—A woman, thirty-five years of age, presented herself with a swelling upon the right side of the tongue. The tumor was the size of a walnut, soft and fluctuating, and not painful on pressure or manipulation. It had appeared, without any known cause, four months previously, had attained its present size in about a month, and then remained stationary. The patient's general health was excellent. Dr. De Brun incised the tumor, which gave exit to a quantity of thin pus. The sac was dissected away and the wound closed with sutures. Union was complete in a few days.—*La France Médicale*, No. 14, 1883.

PURULENT INOCULATION IN THE TREATMENT OF GRANULAR LIDS.—Dr. Terrier formulates the following conclusions to an article on this subject in the *Revue de Chirurgie* for February, 1883: 1. Purulent inoculation is a good method of treatment of old conjunctival granulations with pannus. 2. It is indicated where the pannus is thick. But corneal ulcerations and *pannus tennisi* are contra-indications to its employment. 3. In pannus,

granular or not, affecting one eye, the procedure is to be practised with the greatest care lest the sound eye be inoculated. 4. The pus to be used is that of *ophthalmia neonatorum*. When this cannot be obtained gonorrhœal pus may be employed. 5. No attempt should be made to abort the induced ophthalmia, but it should be treated judiciously, with a view to prevent permanent injury to the cornea. 6. Sulphate of copper, nitrate of silver, yellow precipitate, ointment, or calomel insufflations are frequently indicated in order to complete the cure. 7. In exceptional cases it will be necessary to resort to syndectomy or iridectomy.

SPONTANEOUS GANGRENE IN A YOUNG SUBJECT.—A young man, twenty-four years of age, of healthy appearance, entered the Charité Hospital, suffering from gangrene of the lower extremity. The lower part of the left leg for about three inches above the malleoli was of a livid hue. The foot was of a purplish black color, and the skin upon the dorsal surface was raised in a dark bleb. The temperature of the foot was 72°, while that of its fellow was 96°. Sensibility of the affected member was lost. At the commencement of the trouble there was some fever and anorexia. But this soon passed away, and with the return of appetite the general health seemed good. The origin of the affection was obscure. There was no history of traumatism, but the patient stated that a few months previously he had been obliged to work while standing on the wet ground. About six or eight weeks before his admission to hospital he began to feel a sensation of numbness and formication in the left leg. Soon afterward he found that he was unable to bear his weight upon this limb. The patient appeared to be in excellent general health, and no dyscrasia was discoverable to account for his condition. Examination of the urine gave negative results. By way of exclusion, Dr. Berger was led to attribute the gangrene to an acute arteritis, induced by the prolonged action of damp cold to which the patient had been exposed.—*Gazette des Hôpitaux*, No. 14, 1883.

THE SPLEEN AS A BLOOD-PRODUCING ORGAN.—Dr. Korn has conducted a number of experiments to determine the part played by the spleen and bone marrow in the formation of red-blood corpuscles. He practised repeated small blood-lettings upon pigeons. Changes in the blood after this procedure were constant. It became of a darker color, clotted more readily, and contained a greater number of white corpuscles. The bone-marrow was more red, contained less fat, but presented a very large number of undeveloped red-blood corpuscles. These results were the same whether the spleen had been extirpated or not. When present, this organ was anæmic. Dr. Korn concludes from these experiments that the spleen performs no function in the reproduction of red-blood corpuscles in birds. And in this he is in agreement with Neumann, who has arrived at the same conclusions in respect to animals.—*Deutsche Medicinische Wochenschrift*, No. 6, 1883.

CLIMACTERIC DYSPEPSIA.—Mr. Prangley, in the *British Medical Journal*, describes a form of dyspepsia which he terms climacteric. It occurs in women between the ages of forty and fifty. The symptoms are those of great nervous depression, with pain on the top of the head, noises in the ears, hot flushes and chills, with curious sensations in the abdomen. The dyspeptic symptoms are those of precordial distress, with palpitation, costive bowels, coated tongue, and foul breath. The treatment consists of the administration of bismuth, bicarbonate of potash, and ammonia, adding valerian if the nervous symptoms predominate, followed by quinine, strychnia, and dilute nitro-muriatic acid.

QUARANTINE ON TEXAS BORDER.—The health officers of Brownsville, Texas, have arranged with the Mexican authorities to establish a quarantine at Bagdad.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 12, 1883.

THE CENSORSHIP OF MEDICAL COLLEGES.

THE Illinois State Board of Health has established a reputation as censors of the standing of medical colleges and for energetic work in the matter of regulating the practice of medicine. Despite some serious charges with regard to its action toward the Columbus Medical College, we believe that the Board deserves the good name that it has obtained. Its rulings as to the status of our country's numerous medical institutions have been productive of considerable good. At its recent quarterly meeting the Board resolved to recognize the Indiana Eclectic Medical College and the Joplin Medical College, and not to recognize the diplomas of the United States Eclectic College of this city.

The Secretary, in commenting upon the work of the Board in its relation to medical practice, says:

"Since the last meeting many letters have been received from colleges, both in this and in other States, asking specific information as to whether the Board would recognize diplomas if issued to certain students under the circumstances as detailed. A number of inquiries, both official and personal, have also been answered concerning the standing of colleges in various parts of the country, and the value of their diplomas in this State as entitling to practice. This correspondence marks an increasing sense of accountability in the teaching or educational department, and of its responsibility under the law. If this sense can be sufficiently quickened it may correct some of the evils arising from the want of an examining body independent of the colleges, and there is reason to hope for such result in the progress already made."

The Secretary then refers to the fact that many medical colleges by no means carry out even the minimum requirements announced in their catalogue. Dr. Rauch says:

"As a result of my own official experience during the past six years, I think it entirely within bounds to say that a strict adherence to their advertised requirements is the exception among colleges rather than the rule. In fully three-fourths of those which have come under my observation there have been irregularities of more or less gravity."

We have every reason to believe that there is no exaggeration in the above statements. The announcements made by many medical colleges too often possess the same literary style and moral value that we find at-

tached to patent medicines. In fact, it seems as if the profession greatly needed a body of censors who should inspect our colleges and compare the glittering statements in their circulars with the cold actuality. College corporations are sadly in need of some reminder that the moral law includes them as well as the individual doctor.

In the report to which we have alluded several illustrations of the difference between the letter and the spirit of college catalogues are given:

"An official proceeding required that Dr. —, a graduate of one of the most popular and widely known colleges in the country, detail his acquirements in pharmacy. He was asked what experience he had had in compounding medicines, and replied that he had had none. 'Did you not put up prescriptions under your preceptor while a student?' 'No, sir; I didn't have any preceptor.' 'Why, I supposed that medical colleges required that their graduates should have read or studied medicine under a preceptor for three years. How did you get through? How did you graduate?' 'Well, I attended two courses of lectures, paid the fees and got my diploma.'"

The following communication from Dr. — was received by the Secretary:

—————, ———— Ill.

To the Secretary State board of health Dear Sir I sent you my diploma early last March and have not heard from it since did you receive it or do you know anything about it I am becoming quite anxious concerning its safety My diploma is from ———— Medical College ———— dated ———— 1882 I also sent you a letter containing a one dollar bill to pay for the certificate If you will give me the information I request I shall be greatly obliged to you

Your's very respectfully

————— M. D.

In the annual announcements of the college which issued this diploma, among the regular requirements for graduation one is stated to be "such primary education as is clearly requisite for a proper standing with the public and the profession;" and another that "he must have pursued the study of medicine three years."

Continuing his argument upon this subject, the Secretary makes the following strong statement: "Aside from its legitimate function as a medium of information to the student concerning his studies, the annual announcement, so lavishly scattered throughout the country, is often prostituted to advertising the college and the claims of the individual members of the faculty, in terms and manner differing little, if any, from those of the ordinary advertising quack. In the course of the past six years I have carefully examined nearly all the announcements issued in this country, and do not hesitate to say that many of them are of such a character that if a private practitioner had been guilty of publishing a professional card making such claims and couched in such terms, he would have been expelled from almost any medical society for a gross violation of ethics."

It is scarcely necessary to emphasize the importance of the foregoing. It means that the physicians who are annually flooded with college circulars must read many of them at least with large reservations—a fact which is not creditable to the medical teachers of our country.

THE DIAGNOSTIC SIGNIFICANCE OF VENOUS PULSATION.

THE existence of pulsation in the jugular veins has usually been regarded as of evil prognostic import. It has been held by some authorities to indicate tricuspid regurgitation. Others see in it a sign of insufficiency of the venous valves alone. The former regard it as a ventricular pulse, the latter as one caused by auricular contraction. Nearly all, however, have been agreed in the assumption that it is due to a backward current in the veins. And all have admitted a failure in the venous valves. Bamberger and others even went further, and asserted that the real cause was to be found in a defective auriculo-ventricular opening.

A very careful sphygmographic study of the phenomenon in question has been recently made by Dr. Franz Riegel (*Volkman's Klinische Vorträge*, March 13, 1883). As a result of his labors the author is led to oppose both these views. He contends that a true venous pulse, not transmitted from the neighboring artery, may and often does exist in health. This pulsation is produced not by a backward, but by a forward current. It is caused by the auricular diastole. The blood being drawn in from the distended veins by the suction force of the dilating auricle, there is produced a partial collapse of the vessels, which become again distended during the auricular systole. So that this pulse, indicative of no disease, is really but the expression of the alternately hastened and retarded flow of blood to the heart.

This normal venous pulse may be readily differentiated from that of tricuspid regurgitation by the time of its occurrence. It beats alternately with the carotid pulse. The auricular diastole occurs at the time of the ventricular systole, and consequently the period of arterial fullness corresponds with that of venous collapse. The venous tracing of tricuspid insufficiency begins to ascend prior to the ventricular systole, reaching its highest point just after that of the arterial tracing has been attained. At the ventricular systole the blood is forced backward into the auricle, as well as forward into the pulmonary artery, and the former being thus filled from the ventricle, its diastole causes no venous collapse. It is only when the ventricular diastole occurs that the pressure upon the veins is relieved sufficiently to cause a sinking of the sphygmographic curve. This is the pulse of tricuspid regurgitation, as it occurs when the heart beats with full strength. When the cardiac contractions are weak, a modification of the tracing is observed. In such cases the ventricular contraction is insufficient to fill at once the dilating auricle, and we have a momentary fall in the venous curve. The auricle is more rapidly filled, however, than under normal conditions, and we see in consequence a second rise in venous pressure, the second fall occurring only at the ventricular diastole. The jugular pulse of tricuspid regurgitation with a weak heart is therefore dicrotic.

Still another venous pulse is noted by Dr. Riegel. It is met with in cardiac and pulmonary affections which lead to engorgement of the right side of the heart. The tricuspid valve is here normal, and consequently the pulse corresponds exactly in time with that occasionally seen in healthy individuals. It is a very distinct pulsation, and this is its characteristic. And it is only by its

greater size that it is to be distinguished from the normal pulse. These investigations were conducted apparently with great care, and the conclusions derived therefrom are doubtless correct. But as to their practical value in a diagnostic sense there is room for doubt. Very few practising physicians, we imagine, are provided or will provide themselves with the delicate and expensive apparatus necessary for recording simultaneously the carotid and jugular pulsations. And although the author gives directions for making these observations by the aid of touch and sight alone, the possibility of error in judging of minute fractions of time is too great to render such observations of much value.

THE LATE STATE LEGISLATURE.

THE State Legislature which adjourned last week was, so far as matters of medical interest are concerned, most remarkable for what it failed to do. There are two bills in particular which the profession will regret to learn failed to become laws. These were, the bill providing for a State Board of Medical Examiners, and another making better provisions for the commitment and care of lunatics. There were three bills presented bearing upon this latter subject, and all were lost through some delay, or inadvertance, none of them reaching the stage when they could fairly be beaten in legislative session. A bill abolishing coroners' juries shared the same fate.

It is unfortunately the fact that all bills which contemplate some reform and improvement are most difficult to carry, for, while many are agreed that they are admirable, no particular individual is sufficiently interested to urge the matter systematically. The medical profession is greatly in need of competent representation at Albany.

Among the three or four hundred bills which became laws, there are none which have any medical or sanitary matters, if we except the law which prohibits the manufacture of cigars in tenement houses, and that which regulates the farming out of infants.

It is, perhaps, a matter of congratulation that at least no bad bills were passed, and particularly that no charters for cheap medical schools were given. Some credit is due the Committee on Legislation of the State Medical Society, that this latter was prevented.

PETER AND PASTEUR.

THE opposition to Pasteur and his doctrines has hitherto proceeded chiefly from across the Rhine. It has very promptly been attributed, by his own disciples at least, to national jealousy and Teutonic prejudice. But now an attack has been made upon him from within the camp, and he has been challenged by his own countrymen to substantiate his claim of having materially advanced the science of medicine. At a recent meeting of the Académie de Médecine, Dr. Peter varied the monotony of the customary discussion of typhoid fever, by branching off upon the germ theory of disease and the practical value of Pasteur's researches. He did not attack the germ theory itself; nor would he deny that the discoveries of this investigator had led to most useful and practical results in both obstetrics and surgery. It was to minds inspired by the theories of Pasteur, he said, that we owed the conception of antiseptic surgery. A prevalence

of the same ideas had led to the adoption of certain precautions by means of which puerperal fever had become a far less common disease than in former times. Having said this much, however, he had said all. Further praise would be but flattery.

He maintained that the discovery of the material elements of contagion had, thus far at least, thrown no light upon the pathological anatomy, the evolution, the treatment, or, above all, the prophylaxis of contagious diseases. What, asked M. Peter, is the ultimate object of Pasteur's methods? To attenuate the virus by the action of air and of time, and then to vaccinate with this stale and weakened contagion. Now this is not vaccination at all, he went on to say, but inoculation—a much more serious matter. For the weakened virus is very uncertain in its effects, and is likely to create new centres of contagion. It may even, notwithstanding its "attenuation," induce a mortal disease. The first inoculation, with virus of greatest dilution, does not confer immunity, as Pasteur himself admits. And the second, with strong virus, often kills the animal whose prospective safety it was intended to insure. The admission, by Pasteur himself, that the vaccination was protective only for a limited time, was commented upon in a jocose strain by the speaker, and he pictured to his auditors the woes of the future man, forced to protect himself anew every year, by a course of vaccination, against a multitudinous variety of ravenous bacteria. M. Peter confessed with a chuckle that he had designedly turned the discussion in the Academy from typhoid fever to germs, and he expressed himself as confident of victory in the battle which was now fairly begun. His argument against the utility, or indeed the safety, of Pasteur's vaccinations was a strong one, and was supported by numerous facts. But arguments may be fallacious, and facts are apt to be variously interpreted. Yet, as M. Bouley announced his intention of speaking in defence of this doctrine, in which he is an ardent believer, the discussion bids fair to become an interesting one.

CAN THE MEAN DURATION OF HUMAN LIFE BE PROLONGED?

A most important deduction has recently been made regarding the possibility of extending the duration of human life. In a paper read before the London Statistical Society, Mr. Noel A. Humphreys discussed the question: Has the duration of life in England increased during the last thirty years? It is now nearly thirty years since the late Dr. Farr published his "Life Tables," based on statistics covering a period from 1838 to 1854. His conclusions were that the mean after-life-time of males at birth was 39.9 years, and that of females 41.9 years. According to the new tables presented by Mr. Humphreys, covering the period from 1876 to 1880, this life-period is now for males 41.9 years, for females 45.3 years, representing a prolongation of life of about two years, or a five per cent. increase.

The statistics, when further analyzed, show also that over two-thirds of this prolonged life is for the working period between the ages of twenty and sixty years, thus apparently refuting an assertion which has been widely circulated, that the improvement effected by science consists "in the prolongation of the passive endurance

of life rather than an extension of the power of true vitality, or any increase of the opportunity for good work and for intellectual enjoyment."

These conclusions are, as is remarked by the *British Medical Journal*, well calculated to encourage sanitarians, and to give a fresh impetus to the propagation of the gospel of prophylaxis.

It would be interesting to learn, however, how much of this increase is due to preventing zymotic diseases and how much to an actually greater vital stamina. We suspect that the zymotic factor is the chief one in securing the present favorable results.

News of the Week.

HOSPITAL FOR CONTAGIOUS DISEASES IN BROOKLYN.—Brooklyn Health Commissioner Raymond will address a communication to the Board of Audit at the meeting of that body, to be held on Tuesday next, recommending the insertion in the tax budget of an amount sufficient to erect suitable structures for the treatment of persons afflicted with contagious diseases, and whose means will permit of their paying their own expenses.

THE REJECTION OF DR. CHARLES F. CHANDLER AS PRESIDENT OF THE BOARD OF HEALTH OF THIS CITY.—On Wednesday, Mayor Edson nominated Dr. Charles F. Chandler as President of the Health Board. The nomination was rejected by the Board of Aldermen by a vote of 13 to 10. Mayor Edson, in common with many other friends of sanitary reform, believes that the rejection was due to personal enmity caused by fidelity to duty. Dr. C. had been a faithful officer, and in the exercise of his authority as such naturally gave offence to some who would not willingly submit to sanitary regulations.

THE STATE BOARD OF HEALTH at Albany on Wednesday elected Dr. E. M. Moore, of Rochester, president, and Dr. Elisha Harris secretary. The president reappointed all the committees of last year.

DR. MAURICE KRISHABER, well known as a laryngologist, recently died in Paris.

THE UNIVERSITY OF PENNSYLVANIA has arranged for a voluntary fourth-year course in its medical department.

THE NORTH CAROLINA STATE MEDICAL SOCIETY will meet at Tarborough on Tuesday, May 15th.

REGULATING THE PRACTICE OF MEDICINE IN NEW JERSEY.—The New Jersey Legislature has passed a supplementary act compelling the registration of all persons practising medicine in that State. The provisions for regulating medical practice are now very complete.

THE CARE OF THE INSANE IN PENNSYLVANIA.—It seems that, ever since last January, when it was announced by a Philadelphia editor that the insane of his State were beautifully and lovingly cared for, a succession of charges against various insane asylums and the State lunacy laws have appeared. The latest refers to the Blockley Almshouse at Philadelphia. The mortality among the insane occupants being very great, the matter was investigated by Dr. Richardson. He reports that the sewage from nearly one hundred persons was dumped into the cellar

from which the air-supply was drawn. He also found that the buildings were not properly warmed, the reason being that the boilers were in such a condition that the inspector refused to permit a sufficiently high temperature to be carried to produce the necessary heat.

"We should be glad to know," says *The Sanitary Engineer*, "who is responsible for this disgraceful condition of things. Have they another 'Tewksbury' establishment in Philadelphia?"

DEATH OF DR. HENRY B. WILBUR.—Dr. Henry B. Wilbur, Superintendent of the State Idiot Asylum at Syracuse since its foundation, who died suddenly at the asylum May 1st, aged sixty-three, was a native of Welden, Mass., and the pioneer educator of idiots in this country. He established the first asylum in his own house in 1848. He took charge of an experimental station at Albany in 1851, and of the State institution in Syracuse three years later. He was a graduate of Amherst College, and a physician in his early life. In late years he had been actively concerned in lunacy reform, and was for several years President of the National Association for the Prevention of Insanity and the Protection of the Insane.

MEDICAL COLLEGE OF VIRGINIA.—The Court of Appeals of Virginia, in the case of a petition for *mandamus* to compel the old Board of Visitors to the Medical College of Virginia to surrender to the newly appointed Board full possession of the buildings, property, etc., has rendered its opinion, which is, that Governor Cameron had no authority to appoint a new board under the charter granted the college years ago; that he can only fill vacancies as they occur by death, resignation, removal from the State, etc.; that the Legislature alone has power in the premises to authorize the dismissal of the old, and the appointment of a new board, etc.

This puts the management, says the *Virginia Medical Monthly*, practically in the same hands that it has been in during the past.

THE SUPPORTERS OF BRAND.—Twenty-two physicians of Lyons who believe in and practise the "Brand" method of treating typhoid fever, have tendered M. Bouley a banquet for his eloquent defence of this method, and of Pasteur and experimental medicine, before the French Academy of Medicine.

Reports of Societies.

MEDICAL SOCIETY OF PENNSYLVANIA.

Thirty-fourth Annual Session, held at Norristown, Pa., May 9, 10, and 11, 1883.

(By Telegram to THE MEDICAL RECORD.)

THE delegates had not arrived in sufficient numbers on Wednesday morning to make the opening session of the Thirty-fourth Annual Convention of the Medical Society of Pennsylvania other than the medium for the transaction of routine business.

The Society was called to order at nine o'clock, in Music Hall, the opera house of Norristown, by its President, DR. WILLIAM VARIAN, of Titusville, who made a few appropriate remarks.

In the absence of Rev. Jos. McCaskey, who was expected to offer an opening prayer, the divine blessing was invoked by REV. MR. TWEDELL, of Norristown.

The list of delegates was then read by the Secretary, DR. WILLIAM B. ATKINSON, of Philadelphia, about forty responding to their names.

ADDRESS OF WELCOME.

An address of welcome was then delivered by DR. HIRAM CORSON, of Norristown, after which the Committee on Arrangements reported the programme.

REPORTS OF DELEGATES AND COMMITTEES.

The report of the delegates from the Society of Pennsylvania to the American Medical Association at St. Paul last year, signed by Dr. William Varian, the chairman of the delegation, was then read and adopted. Dr. Marshall was introduced as a representative of the Delaware State Medical Association. Dr. William B. Atkinson, of Philadelphia, the Committee on Publication, then reported that the proceedings of the last meeting of the Association at Titusville had been duly printed.

PRELIMINARY MEDICAL EXAMINATIONS.

The report of DR. O. H. ALLIS on schedule of subjects for preliminary medical examinations was then read. After some debate, it was referred to a committee of one from each county society.

The reports of the various county medical societies were then read and referred. As an amendment to the printed rules, it was resolved that they be so amended as to allow a suspension of the rules by a two-thirds vote of the members present.

ENDORISING THE CODE OF ETHICS OF THE AMERICAN MEDICAL ASSOCIATION.

Under the head of New Business, Dr. H. H. Smith, of Philadelphia, offered the following:

Resolved, That the State Medical Society of Pennsylvania reaffirms its approval of and adhesion to the Code of Ethics adopted by the American Medical Association.

Resolved, That organized opposition by a local society and by individuals to the Code approved by the medical profession of the United States is rebellion against the constituted authorities, and should be so treated.

Resolved, That the Secretary be instructed to forward a copy of these resolutions to the Committee of Arrangements at Cleveland, O., for presentation to the Association.

DRS. W. ATLEE and F. WOODBURY, of Philadelphia, and E. PALLER, of Athens, spoke on the resolutions, in the passage of which much interest was manifested. The resolutions were carried, after which thanks were returned to Dr. Corson for his address.

DR. BENJAMIN LEE, of Philadelphia, made some remarks upon the affection known as

WRITERS' CRAMP,

or writers' palsy. He considered that these were two distinct affections, the one a true cramp, the other a paralysis, or rather an exhaustion of certain muscles of the arm and hand. Both were recognized by physicians as being very intractable, especially when they have existed for a considerable length of time. A number of appliances have been invented to enable persons suffering from them to hold and use the pen. Dr. Lee presented two such, one a modification of his own of the instrument devised by the famous French surgeon, Velpeau, which he considered as more applicable to those cases in which exhaustion or paralysis was the prominent feature. It consisted of a pear-shaped piece of wood, to be held in the palm of the hand, with a shank passing down to the end of the index finger, to which are attached metallic rests for the fingers and thumb and rings to hold the first two fingers firmly in the instrument; the pen is held below the index finger in very nearly the ordinary position. The other had been introduced to the profession by Professor Nussbaum, of

Munich, during the past year, and is called by him bracelet for writers' cramp. In Dr. Lee's experience it was especially adapted to those cases in which a true cramp is the prominent feature of the case. The one exhibited was imitated from a pattern sent from Germany and made under the inventor's direction. It consisted of a thin band of hard rubber, about an inch and a half broad and large enough to take in the thumb and three fingers when stretched out quite straight. On the back of this band the pen was attached in such a way that its direction to the paper and length could be regulated. Professor Nussbaum's theory was that the extensors of the fingers were the seat of the disease and not the flexors, as usually supposed, and he believed that this appliance would, by compelling the extensors to act, not only prove a means to enable the patient to write, but also aid in curing the disease. Dr. Lee read an extract from a letter from a patient who had been using this bracelet for several months, in which he testified to the ease with which he was enabled to write by its means. Specimens of the patient's writing, both with and without the bracelet, were shown and fully sustained his favorable report.

At the opening of the afternoon session, DR. WILLIAM M. WELCH, of Philadelphia, read by request his voluntary paper on the

WEARING OUT OF VACCINE PROTECTION

and the efficacy of revaccination, Dr. James Tyson, who was to deliver the opening address of the afternoon, not having arrived at that hour. The substance of the address of Dr. Welch, who is the physician in charge of the Municipal Small-pox Hospital, was as follows:

Jenner's belief in the identity of small-pox and cow-pox has led to experiments by Thiele, Bodcock, Voight of Hamburg, and others who have successfully transformed variola virus into vaccine in the body of the bovine animal.

The belief in the identity of variola and vaccinia led to the idea that they can be communicated to a person but once in a lifetime. Jenner believed that vaccination was as complete a preventive of small-pox as one attack of that disease was of another. Learned Medical Societies, in the early part of this century, emphatically denied with Jenner the necessity of revaccination. However, although very many physicians still believe in the absolute efficacy of early vaccination, which leaves a well-defined cicatrix, I am convinced of the fallacy of this, and propose to show, first, the susceptibility to small-pox, however thoroughly destroyed by vaccination, may subsequently return; second, revaccination can be depended on to destroy this return of susceptibility to the disease.

The first epidemic of small-pox that occurred after vaccination was in general use appeared in Scotland, in 1818. This epidemic, however, did not convince the profession of the necessity for revaccination, though it gave rise to the term varioloid. In 1824, another such epidemic, attacking many persons vaccinated in early life, appeared all over Europe.

The British Government began the employment of public vaccination in Ceylon before 1819, but in that year as well as in 1830, 1833, and 1836, a violent epidemic overspread that island, attacking many who had been vaccinated. Between 1824 and 1835, 3,839 cases occurred in Copenhagen, of which 3,093 occurred among persons who had been vaccinated, although the death-rate among the latter was only 2.13 per cent.

The statistics of small-pox hospitals show that a large proportion of cases occur among persons who have been vaccinated in early life. In 7,326 admissions to the London Small-Pox Hospital from 1855 to 1865, 78 per cent. occurred after vaccination. In my own experience, during the great epidemic of 1871-2, 2,377 cases were admitted into the Philadelphia Municipal Hospital, of which 68 per cent. occurred in persons vaccinated in early life. In the epidemic of 1880-81-82, there were 1,059 ad-

missions, of which 54 per cent. were post-vaccinated cases, the proportion being 14 per cent. less than before, owing to the greater use of vaccination in Philadelphia at that time.

I shall also show that this deterioration of vaccine protection is progressive, increasing up to a certain period of life with the length of time since vaccination. Between January 1, 1871, and May 1, 1883, I observed 2,507 cases of post-vaccinal small-pox. Under the age of five years there were 10 cases and 2 deaths, from 5 to 10 years there were 46 cases and 8 deaths, from 10 to 15 years there were 99 cases and 8 deaths, from 20 to 25 years there were 745 cases and 96 deaths. The percentage of deaths in the total number of 2,507 cases was 16.89 per cent. It is evident, therefore, that while at first affording almost complete protection, as children approach the age of puberty there is very great deterioration of vaccine protection. The tables prove that the maximum number of post-vaccinal cases occurs at the period immediately following puberty.

I am also convinced that vaccine virus not only loses much of its vigor through a long series of human transmissions, but also suffers in the durability of its prophylactic power.

When a public vaccinator in Philadelphia, from 1867 to 1870, I found it necessary to visit my patients, for the purpose of collecting crusts for future use, on the fourteenth or fifteenth day after inserting the virus. The appearance of the vaccine scar always determines, as a general rule, the character of the vaccination a person has received. A permanent scar, distinct as if stamped with a die, shows proper vaccination. As a general rule there is a direct relation between vaccine cicatrices and the prophylactic power. The protection which results from vaccinia of short duration is not so durable as that which results from vaccinia of a perfectly typical character. Long humanized virus produces less favorable results than bovine lymph or that of recent humanization.

Successful revaccination modifies, of course, the resulting vaccinia. As varioloid differs from small-pox, so does the vaccioid resulting from revaccination differ from true vaccinia. Every epidemic has proven the virtues of revaccination, the time for which is shown by the tables from which extracts have already been made. Vaccination is nowhere so carefully performed as in Germany, and there the efficacy of revaccination has been proven. In the twelve years of my experience no one connected with the Municipal Hospital who was properly revaccinated had the small-pox. If vaccination be effectually performed in infancy, and revaccination at puberty, we would begin to realize that small-pox may be extirpated from the earth.

DR. R. L. SIBBETT, of Carlyle, then read a voluntary paper on "Obstetrical Notes." He was followed by DR. HUGH HAMILTON, of Harrisburg, who read a paper with many charts upon artificial infant alimentation, in which he recommended mixed healthy cow's milk neutralized with bicarbonate of soda and with an addition of one or two tablespoonfuls of good cream, according to age, heated to 55° C. (131° F.), and sweetened with a freshly made syrup of milk sugar.

ADDRESS ON MEDICINE.

DR. JAMES TYSON, of Philadelphia, Professor of Pathology and Morbid Anatomy in the University of Pennsylvania, was then called upon to deliver his address on "Medicine," the substance of which was as follows:

Perhaps the most important form of hæmaturia and hæmoglobinuria resulting from general causes is that due to malarial poisoning.

The first complete report of an undoubted instance of this affection appears to have been published by Dressler in 1854, although incomplete and uncertain cases were reported prior to this date, one as early as 1832 by Elliotson. Two degrees of the disease are met with—a milder form, in which other symptoms as well as the

hæmaturia are less pronounced, and of which instances occur in the Middle States as well as the South and West of this country; and second, a more malignant form, attended by great prostration, vomiting, etc., yellowness of the skin, along with copious discharges of bloody urine.

While a majority of cases of malarial hæmaturia are intermittent many are continuous, and of my seven cases, only two were distinctly intermittent. One of these cases I published in a clinical lecture in the Philadelphia *Medical Times* as far back as September 1, 1871.

The pathology of malarial hæmaturia consists, as yet, chiefly of theoretical deductions. We can only conclude that the malarial poison acts upon the blood and blood-vessels, impairing the integrity of both. This goes so far, occasionally, as to produce an actual destruction of blood-disks, and always so alters the capillaries that they permit the transudation of blood-elements ordinarily retained.

The treatment is distinctly that of malarial disease, and I have seldom seen more brilliant and satisfactory results than have followed the use of quinine, in a case accurately determined; although such results are not invariable, and I have known the disease to resist for a long time the most thorough and judicious use of anti-malarial remedies. Usually, however, I take hold of a case of this kind with considerable confidence; when there are distinct remissions, my practice has been to administer sixteen to twenty grains of sulphate of quinia, in the usual manner of anticipation of the paroxysm in intermittent fever, from three to five grains every hour until the required amount is taken. The whole amount may be taken in two doses, or even in one dose. Where there is no distinct remission I more usually direct three to five grains every three hours until the hemorrhage ceases or decided cinchonism is produced.

The second more serious form of this disease, as it appears in the tropics and in the southern part of the United States, is characterized by such increased intensity of all the symptoms that it may be well called "malignant." Singularly, however, the disease has seemed to be much more prevalent during the last fifteen years. My attention was first called to it in September, 1868, when I received specimens of urine and the history of some cases from Dr. R. D. Webb, of Livingston, Alabama, who wrote also that it was not known in that part of his State, at least prior to 1863 or 1864.

The treatment for the breaking of the paroxysm is pre-eminently quinine, or quinine with mercurials, and although this does not always succeed, there seems to be no other remedy. It has been given hypodermically. The nausea has been controlled by morphia and lime-water, by carbolic acid and by creosote. In addition restorative measures are necessary, including the free use of stimulants. Turpentine has been used in large doses, it is said, with advantage in Alabama.

R. H. CHASE, Superintendent of the male department of the Norristown Asylum, then read a very interesting address on

INSANE ASYLUMS IN SOME OF THEIR RELATIONS TO THE COMMUNITY.

He alluded to and ridiculed the sensational stories of the confinement of sane men in insane asylums, which he thought utterly impracticable. He mentioned the case of Dr. Sevin, of Erie, whose story of his confinement in Dixmont, resulted in the legislative investigation of that institution; and another which came under his own observation. He said such charges reflected on men and institutions which were an honor to the State and deserved better things. The sensational charges made in such cases were contrary to common sense.

DR. DE F. MILLARD then read an address on

SIMPLE METHODS OF TREATMENT OF CLUB-FOOT,

giving practical illustrations on a living subject of the nature and use of proper mechanical appliances. The use of

gypsum as a setting and of elastic force were commended. The utility of the forms of rubber known as "printer's blanket," "gum soling," and of gutta-percha when moulded in hot water, as well as of sole-leather as supporting bands was then shown. All these papers were referred to the Committee on Publication.

In the general discussion of the papers, DR. STEWART, of Erie, said that if a one-hundredth part of what was published about Dr. Sevin were true it would cast odium on every institution for the insane in the United States. He would stake his professional reputation that Dr. Sevin was insane when committed to Dixmont. He had never made any complaint to him, Stewart, when the latter had visited him, and was still insane to-day.

DR. WILLIAM ULRICH, of Chester, said that the only paper which had been read at the recent meeting of the Society for the Protection of the Insane in Philadelphia, which favored the popular sentiment that sane persons are confined in insane hospitals, was by Dr. Heber Newton, of New York, and his paper met with such a savage reception that he did not think Dr. Newton, who was not a physician, would venture soon to seek notoriety outside of New York.

DR. HIRAM CORSON, of Norristown, said there were some cases of sane people confined in asylums, and he knew of harmless people who might well be at home, but who are in asylums. In some cases husbands pay largely to have their wives confined. There should be a home for convalescents in connection with every asylum, a home which is not a hospital or an asylum.

DR. ULRICH said that physicians did not always distinguish between insanity and drunkenness. He knew of one man in Philadelphia who was committed as insane (when drunk) thirteen times and discharged as cured thirteen times.

DR. SCHULTZ, of the Danville Asylum, said the laws of Pennsylvania made it very easy for a patient to get out of an asylum. He showed how outside parties could get a man out of an asylum, but did not show how a patient could get out, if unlawfully confined, without powerful outside aid.

DR. CORSON again spoke of the difficulty with which a woman could get out of an asylum. He had been trying to get a married woman out of a Pennsylvania asylum for a year and a half; her sister wanted her out to live with her; her so doing would benefit the sister and would be a saving of twenty dollars a week to the husband, yet the husband, the power behind the trustees, would not let this woman out, and no one could say how she could get out, though she was mild, intelligent, harmless, and cultivated.

An adjournment was had about 4.30 o'clock, until 7.30 o'clock.

ANNUAL PRESIDENTIAL ADDRESS.

Quite a number of the citizens of Norristown, the visiting medical men and ladies gathered in the Court House at 8 o'clock to hear the annual address of the President of the Society. Dr. Varian was introduced by Dr. Addinell Hewson, of Philadelphia, First Vice-President of the Association. The substance of Dr. Varian's address was as follows: The Medical Society of the State of Pennsylvania was organized thirty-five years ago in Lancaster. Now there is an active living society in almost every one of the sixty-six counties of the State, with a total membership in the State Society of nearly eighteen hundred. The main objects of the great Society are now to obtain efficient Legislation in behalf of State Hygiene, the proper draining, building, and lighting of dwellings, and legislation for hospitals for the insane, feeble, and sick.

But charlatantry, superstition, and ignorance still roam almost unchecked throughout Pennsylvania. Its physicians and people need a State Board of Health. It is time that, in regard to burial, sentiment should yield to common sense. All refuse matter, whether animal

or human remains, should be cremated. Let the crematory take the place of the cemetery. Again, how can the inebriate be restored to moral, mental, and physical health, thus reducing crime sixty or so per cent.? The penitentiary has proved ineffective. The asylum, in its proper development, will doubtless answer the question.

In the great question of vaccination there should be expert inspection and control of animal vaccine as a protection against diseases scarcely less to be dreaded than small-pox itself.

In the matter of medical education, a Chair of State Medicine and Hygiene should be established in every medical school, and three full years of attendance should be required before a diploma is granted.

The action of a medical society of a neighboring State in throwing down the barriers which have been so long maintained between the science of medicine and legalized dogmatism, received from you at your last session an expression of unanimous disapproval. The renewal of that action demands a renewal of your disapproval.

MICHIGAN STATE MEDICAL SOCIETY.

Eighteenth Annual Meeting, held at Kalamazoo, Michigan, May 9 and 10, 1883.

(By Telegram to THE MEDICAL RECORD.)

THE Michigan State Medical Society began its eighteenth annual meeting May 9th, in the Kalamazoo Academy of Music, President GEO. TOPPING, M.D., of Dewitt, in the chair.

ADDRESS OF WELCOME.

After prayer by the REV. GEO. F. HUNTING, the HON. E. W. DEVOE, President of the Village, gave an address of welcome, to which President TOPPING responded briefly on behalf of the Society.

REPORT OF EXECUTIVE COMMITTEE.

DR. FOSTER PRATT, Chairman of the Executive Committee, gave his report. He announced that all the medical gentlemen with their ladies were invited to a reception tendered by the citizens of Kalamazoo and by the local medical society at the Burdick House, on Wednesday evening. He also read an invitation to the gentlemen from Superintendent Palmer to visit the Michigan Insane Asylum, and another from the president and secretary of the village to inspect the various departments of the village.

REPORTS OF COMMITTEES.

The Secretary, DR. GEO. T. RANNEY, read his annual report, and also that of the Committee on Publication. The present number of members of the Society is two hundred and sixteen.

DR. SMART, the Treasurer, reported a balance in the treasury of \$429.26.

ANEURISM BY ANASTOMOSIS.

DR. WM. BRODIE reported a case which had recently come under his observation. The patient, a healthy German woman, aged forty-seven, still menstruating, mother of several children, slipped one day upon the sidewalk, striking upon the back of the head. She was stunned by the fall, but soon recovered therefrom. She had not noticed, however, a swelling over the occiput, which slowly increased in size. When Dr. Brodie first saw the patient this swelling had reached the size of a goose-egg. He discovered several smaller tumors over the scalp. Auscultation revealed a bruit. There were no pulsations. A bistoury, plunged into the tumor carefully, allowed a free escape of arterial blood. The wound was closed, erysipelas set in, and it seemed at one time impossible to save the patient's life. She recovered from this, however. The diagnosis of diffuse aneurism was

made. For treatment, pressure was not considered expedient. Ligation of arteries was rejected on account of the free anastomosis of the arteries involved. Electrolysis was advised, but the patient did not wish to try it at present.

DR. GEO. RANNEY read the list of applications for membership.

In the afternoon session THE PRESIDENT read the annual address. He lauded the work of the State Board of Health, and urged the profession to assist them in their efforts to control disease. He called attention to the rapid increase in the proportion of doctors to the population, and in that connection lamented the State support of medical schools. He remarked that the low lecture fees was an inducement to men to enter the profession who would otherwise be content in humbler spheres. The free hospitals in connection with the schools treated at public expense many who were perfectly able to pay for treatment. The portion of the president's address relating to the University was referred to a committee to report upon on Thursday.

DR. C. J. LUNDY, of Detroit, read a paper upon

ERRORS OF REFRACTION AND THEIR RELATION TO CONSTITUTIONAL SYMPTOMS.

He gave a series of cases in which patients complained of headaches, such as have been generally thought to be due to uterine disease, consisting of pain in the vertex and at the lower occipital region. In all of the cases related, after fitting proper glasses to the eyes, the other symptoms disappeared. He also spoke of errors of refraction causing retinal congestion. He called attention to the fact that many persons wear colored glasses for retinal hyperæmia, which is made worse thereby, when if the errors of refraction were corrected they would not need the colored glasses.

DR. CONNER, in discussing the paper, mentioned two cases which had come under his observation. In one physician astigmatism had so excited the brain as to produce insanity, which disappeared after wearing glasses. In the other, after correcting errors of refraction, epileptic attacks had grown less severe and less frequent.

DR. T. W. REYNOLDS read a paper on

TIMELY CATHARSIS.

He recommended the use of cathartics in the early stages of lobar pneumonia; he had aborted an attack of rheumatism by free catharsis, the same result had been reached in one case of trifacial neuralgia, and in the delirium following cranial injuries. He recommended three drops of croton oil in water; he used the same for puerperal mania, violent hysteria, and uræmia. He did not discuss the abuse of cathartics. For mild action he recommended a glass of warm water, or a cup of coffee in the morning. In the discussion following, attention was called to the fact that free catharsis did not necessarily imply that the bowels had been emptied; in one case mentioned about a peck of fecal matter had been removed after catharsis.

(To be continued.)

THE TWELFTH CONGRESS OF THE GERMAN SURGICAL SOCIETY.

Held in Berlin, April 4, 5, 6, and 7, 1883.

PROFESSOR V. LANGENBECK, PRESIDENT, IN THE CHAIR.

(Special report for THE MEDICAL RECORD.)

THE President, DR. VON LANGENBECK, opened the Congress with the report of the committee on the award of the prize offered by the Empress for the best essay upon "Experimental Investigations upon the Etiology of Diphtheria, and Practical Conclusions derived therefrom." The Committee reported that of twenty-three competing essays, only a few were in any way worthy of considera-

tion; and even the essay to which the prize was awarded was worthy of it only in its first part, and accordingly it was for this part only that the prize was given. The author was Professor Heubner, of the University of Leipzig.

On motion of DR. BARDELEBEN, Professor von Langenbeck was re-elected President of the association.

After the election of officers the scientific work of the Congress was begun by DR. KOCHER, of Berne, who read a paper entitled

EXTIRPATION OF BRONCHOCELE AND ITS RESULTS.

The chief difficulties met with in the operation were the avoidance of injury to the recurrent laryngeal nerve and the arrest of hemorrhage. The author advised the ligation of the veins prior to that of the arteries. Dr. Kocher did not now perform tracheotomy, as advised by Rose, for he considered it a harmful procedure as tending, through incision of the cartilages, to increase the bend of the trachea caused by the lateral pressure of the goitre. It was allowable only in case the danger from suffocation was imminent. He held that the total extirpation of the goitre was injurious to the organism, especially during the period of growth, and he thought there was some relation between so radical a measure and cretinism or idiocy. The unfavorable results of the operation were seen in a feeling of weakness and a constant chilliness, in slowness of thought, of speech, and of movement, and also in a swelling of the hands, feet, abdomen, and especially of the face. These latter gave to the patient the appearance of one suffering from Bright's disease, though there was no albuminuria. There was anæmia in a high degree, as evidenced by microscopical examination. To this ensemble of symptoms the author gave the name of *cachexia strumipriva*, while the anæmia following the extirpation of the spleen is but temporary and appears immediately after the operation, this *cachexia strumipriva* is a progressive and truly pernicious anæmia, which is developed only some time after the operation. The author concluded from this that the thyroid gland was a blood-producing organ, or at least that it aided in the formation of blood. He thought also that possibly it was a regulator of the cerebral circulation. The atrophy of the trachea following the operation was worthy of note. It was probably due to the ligation of the superior and inferior thyroid arteries. In conclusion, he stated that, as a rule, the gland should never be totally, but only partially, removed. His conclusions were based upon a study of one hundred and two operations.

A second paper on

EXTIRPATION OF THE THYROID GLAND

was read by DR. BARDELEBEN, of Berlin. The author confined his remarks to a short report of four cases of goitre, recently operated upon by him, as he feared the paper prepared by him would appear insignificant after the one just listened to. He denied that unfavorable results necessarily followed upon the total removal of the tumor, as in two of his cases he had met with unequivocal success. On the contrary, he thought that the very cachexia observed by Kocher would have appeared had no operation been performed. He had never had recourse to tracheotomy. He opposed the theory that extirpation of the spleen and thyroid gland, as being blood-forming organs, was of evil influence upon the organism. He had removed the spleen and thyroid gland in a dog several years before, and had observed no unfavorable consequences.

DR. MAAS, of Freiburg, presented the third paper, entitled:

CHANGES IN THE TRACHEA INDUCED BY BRONCHOCELE.

He had never observed a connective-tissue degeneration, such as is described by Rose. He had, however, met with a bending of the trachea caused by the tumor,

and by reason of which tracheotomy was rendered necessary. He had also seen two cases of posterior dislocation of the trachea caused by unilateral goitre. Whenever these patients bent the head forward, asphyxia arose. Both were cured by extirpation of the goitre. Dr. Maas had never performed tracheotomy in the operation for removal of goitre, nor had he ever performed the latter operation except in case of urgent necessity. In 522 cases of goitre treated by him, he had excised the tumor only 23 times. In all the other cases he had obtained a diminution in the size of the tumor by treatment with iodoform.

DR. MAAS also read a paper on

THE ALKALOIDS OF DECOMPOSITION.

He referred to the investigations of Thiersch, Bergmann, and others, and stated that he also, by a process, the principal steps of which he described, had found alkaloids of very poisonous properties in decomposing animal matter. These substances were found in a body as early as twenty-four hours after death; they were present in great quantity. The author had found three alkaloids of differing action. The first, in very small dose, induced a most marked tetanus, and in larger doses caused the death of the animal in thirty or forty minutes. The action of the second resembled that of morphia, and the third simulated strychnia in its effects. These researches would indicate that we may have diseases following a wound which are referable to poisoning from the alkaloids in question.

DR. VON BERGMANN remarked that in the preceding Congress he had noted the difference between a putrid infection caused by the poison of decaying animal matter and septicæmia induced by the presence of microorganisms in the blood.

DR. MAAS stated that Brieger had obtained an alkaloid by treatment with amyl alcohol, whose action exactly corresponded to that obtained by himself.

DR. BOEGEHOLD, of Berlin, presented an article on

INJURIES OF THE THORACIC DUCT.

This was followed by a report by DR. BRUNO SCHMIDT, of Leipzig, on

THE RESULTS OF HERNIOTOMY SINCE THE INTRODUCTION OF THE ANTISEPTIC METHOD.

In 308 cases of strangulated hernia, operated upon in various hospitals from 1875 to 1881, the mortality was 36.6 per cent. The mortality of operations undertaken previous to the introduction of Lister's method was 45.8 per cent., showing a difference of only 9.2 per cent. In spite of any antiseptic precautions, he thought the mortality would always correspond to the severity of the operation. The field of the operation was itself a septic one, and such precautions could reduce the proportion of deaths no further. In view of these facts the removal of the immediate danger of death only should be attempted, and the radical operation should not be ventured upon. In the case of gangrene an artificial anus should be made, and only after an interval should the suture of the gut and its reposition be attempted.

DR. GUSSENBAUER, of Prague, differed very decidedly from the author. He stated that the results of 160 operations, collected by one of his assistants, made an excellent showing for antiseptics. The results depended not so much upon the nature of the operation as upon the condition of the cases operated upon. Even a simple reposition of the intestine might eventuate fatally if peritonitis were already present.

DR. ZELLER, of Berlin, related

A CASE OF MELANURIA,

occurring in Von Bergmann's clinic. The patient, a man forty-three years of age, was suffering from multiple

melanotic sarcoma of the skin, and died, six weeks after coming under observation, with cerebral symptoms. The urine was clear, of a dark brown color, and contained a large amount of hydrobilirubin. He thought the coloring matter of the urine was to be referred to two sources. One was the coloring matter of the blood or bile, the other the substances formed in the digestion of albumen in the intestine.

(To be continued.)

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Eighty-fifth Annual Convention, held at Baltimore, April 24 and 25, 1883.

(Special Report for THE MEDICAL RECORD.)

(Concluded from p. 467.)

MEDICAL BIBLIOGRAPHY—TARNIER'S FORCEPS—ANTI-PYRETIC EFFECTS OF CARBOLIC ACID AND ASTRINGENT INFLUENCE OF RUBUS PROCUMBENS—ACTION OF ALCOHOL ON THE HEART—SUBCUTANEOUS NERVE-STRETCHING—INCREASING USE OF NARCOTICS—SPONTANEOUS COW-POX IN BALTIMORE COUNTY—NASO-AURAL CATARRH AND ITS TREATMENT—ELECTION OF OFFICERS.

DR. JOHN S. BILLINGS delivered the annual oration, choosing for his subject "Medical Bibliography." He gave a historical review of medical bibliographical work, and then described the library at Washington, its objects, and the future plans regarding it.

In the Section on Obstetrics and Gynecology, DR. WILLIAM T. HOWARD read a paper on Tarnier's forceps, which he highly praised.

In the Section on Materia Medica and Therapeutics, DR. JOHN S. LYNCH presented a paper entitled "Observations on the Antipyretic Effects of Carbolic Acid, and upon the Astringent Influence of Rubus Procumbens." Carbolic acid in large doses (gr. v., q. two to four hours), was thought to be highly potent as an antipyretic in essential and inflammatory fevers. He combined aconite with it. Typhoid fever rarely lasted over fourteen days, if treated with this drug. In septicæmia and in hectic phthisis it was also recommended.

Rubus procumbens, or dewberry root, was a drug which had never failed him in diarrhoeas of all forms. It was a specific for the summer diarrhoea of infants. The dose for adults was a drachm of the fluid extract.

PROFESSOR H. NEWELL MARTIN read a paper entitled the "Direct Action of Alcohol on the Heart." The reader had experimented upon the isolated mammalian heart, and upon a man previously a total abstainer.

First, from a Marriott's flask defibrinated blood was fed to the heart, then blood containing absolute alcohol, and after this good blood again. The results of these experiments demonstrate: 1. Alcohol in the above doses has no influence on the pulse. 2. As regards the work done by the heart in a minute, blood containing one-eighth per cent. of alcohol is without effect, at least for five or ten minutes; but blood containing one-fourth per cent. of alcohol nearly always, and that containing one-half per cent. always greatly diminishes the work done. If the supply of alcoholized blood be not too long continued, the heart can be recovered by feeding anew with pure blood. 3. The diminution of work is due to an alteration in the elasticity of the cardiac muscle, in consequence of which the heart swells out so that even in its systole it nearly or quite fills the pericardial bag. Hence in diastole it cannot dilate farther to receive a fresh supply of blood. 4. If the pericardium be removed, the above doses of alcohol are without effect on the work done, at least for a considerable time; the heart, however, swells enormously and beats in a quite unphysiological manner, never obliterating its ventricular cavities in systole.

DR. J. D. ARNOLD read a paper upon "Some Forms of Laryngeal Paralysis."

DR. R. B. GUNDRY read a paper on "The Prognosis of Insanity," which was very well received.

DR. J. W. CHAMBERT read a report upon the subject of "Subcutaneous Nerve-stretching for Sciatica." The author concluded that in most cases the operation was promptly efficacious.

DR. TIFFANY exhibited a girl, aged thirteen, from whom he had excised the upper jaw from the left incisor to the second right molar tooth, for a sarcomatous tumor originating in the socket of an undeveloped right lateral incisor.

DR. G. HALSTEAD BOYLAND read a paper upon the "Increasing Use of Narcotics"—opium, chloral, bromide of potassium, etc.—and the evils resulting therefrom, and urged the need of legislation to regulate their sale. After reviewing the legal status of the subject in other States and countries, he proposed a law rendering it unlawful "to sell, give, or dispose of any poison or poisonous substance, except upon the order or prescription of a regularly authorized practising physician, under penalty of a fine not exceeding \$25 for the first offence, nor \$50 for each succeeding offence." The act not to extend to wholesale dealers.

DR. ST. GEORGE W. TEACKLE, State vaccine agent, related the facts connected with a case of spontaneous cow-pox in Baltimore Co., and the result of experiments with crusts obtained therefrom. This alleged vaccinia appeared about the middle of January last upon the udders of a herd of Alderneys on a farm about six miles from Baltimore. Four cows were affected. Careful investigation excluded all possibility of inoculation.

DR. JOHN N. MACKENZIE read a very elaborate and valuable paper on "Naso-Aural Catarrh and its Rational Treatment." The author insisted upon the great frequency of reflex cough as a symptom of disease; in his experience it has become so common that he has long since ceased to regard it as a curiosity. *His clinical experience furnishes abundant proof that the cough occurs only when from a local pathological process, or ab-extra stimulation, irritation of the turbinated corpora cavernosa of the nose exists.* He has furthermore succeeded experimentally in localizing the area of reflex excitability in the mucous membrane covering these erectile bodies. Repeated experiments also show that all parts of this sensitive area are not equally susceptible to irritation, and that the cough is most constantly produced by artificial stimulation of the membrane clothing the posterior end of the inferior turbinated bone, and that of the erectile body on the septum immediately opposite. In other words, there exists in the nose a reflex sensitive area analogous to that discovered in the larynx by Stoerk, Vulpian, and others. Apart from its physiological interest the practical importance of this fact in a diagnostic and therapeutic point of view is sufficiently obvious; in it is found the explanation of many obscure cases of cough which heretofore have received no satisfactory solution, and its recognition, therefore, is the key to their successful treatment.

Dr. Mackenzie describes further on a forceps he has invented for the removal of adenoid growths.

The following officers were elected: *President*, Dr. Richard McSherry; *Vice-Presidents*, Drs. W. Stump, Forwood, and John S. Lynch; *Recording Secretary*, Dr. G. Lane Taneyhill; *Assistant Recording Secretary*, Dr. Robert T. Wilson; *Corresponding Secretary*, Dr. W. F. A. Kemp; *Reporting Secretary*, Dr. Richard H. Thomas; *Treasurer*, Dr. Judson Gilman.

On motion of DR. WILLIAM LEE, a resolution was adopted reaffirming allegiance to the Code of Ethics of the American Medical Association.

After the adoption of a vote of thanks to the authorities of the Johns Hopkins University, and a complimentary vote to the late President, the Faculty adjourned *sine die*.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 11, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. W. M. CARPENTER presented, in behalf of a candidate, a specimen of *ovarian cyst*.

DR. J. A. WYETH presented a specimen which illustrated

THE CAPABILITY OF THE JUGULAR VEIN FOR DISTENTION.

It was taken from a subject injected with plaster-of-Paris, and the vessel, just at the point where the common carotid is crossed by the omohyoid muscle, had a circumference of about three inches. The point of interest in the specimen was that the veins become distended when free circulation is obstructed, and thus the internal jugular may become so distended that it will overlap the arteries, and hence easily be wounded in cutting down upon the common carotid artery for purposes of ligation.

Dr. Wyeth also presented the tooth of some animal that probably lived in one of the former geological periods. It was sent to him by a former student from Randolph, Tenn., who found it on a sand-bar in the Mississippi River.

DR. WM. P. NORTHRUP presented a specimen of

CIRRHOSIS OF THE LIVER IN A CHILD FOUR AND ONE-FOURTH YEARS OF AGE.

The child died at the New York Foundling Asylum of scarlatina and diphtheria. Autopsy showed hob-nailed liver, and for this lesion the case was reported. The history was furnished by Dr. G. M. Swift, House Physician.

January 19th.—Whooping cough.

January 30th.—Eruption of scarlatina.

February 6th.—Diphtheritic membrane in the pharynx, profuse discharge from the nose; later, croup and extensive sloughing of pharynx. Death occurred eighteen days from the appearance of the scarlatina, and nine days from the appearance of the exudation upon the walls of the pharynx.

Autopsy eleven hours after death.—Body, well nourished; excoriations about lips, nose, and ears. Brain, normal. Pharynx, sloughing; naso-pharynx in like condition. Larynx: Epiglottis and its folds cedematous; chink nearly closed when viewed from above; diphtheritic membrane over inner surface. Trachea: granular fibrin upon a deeply congested base. Lungs: moderate general edema; scattered lobules of broncho pneumonia; bronchi deeply congested. Heart: about one ounce of clear fluid in the pericardium; heart-tissue normal; ventricles in diastole, filled with dark- and light-colored clots. Liver: somewhat diminished in size, thicker than normal, shortened in antero-posterior measurement, edges rounded; upper surface distinctly mammillated and tuberculated ("hob-nailed"), marked with dilated vessels; in the depressions the capsule has a translucent, gelatinous appearance; color of liver *café-au-lait*; consistence firm and unyielding, "cries" when cut with a knife; cut surface shows an indistinct reticulation, the spaces enclosing an area about the size of a millet-seed; gall-bladder moderately distended with light-green bile. Spleen: size small; outer surface normal; when cut, shows dry tissue thickly studded with Malpighian bodies, which appear somewhat enlarged and white. Kidneys: congested; firm; size normal. Stomach: uniform redness; increase of mucus. Intestines: mesenteric glands somewhat enlarged; dusky. Small—Peyer's patches congested, and in lower portion of ileum swollen; contents normal. Large—solitary follicles enlarged; white; contents dark, grumous.

Microscopic examination.—A section transverse to and including the upper surface of the liver gives a crenate margin. Within the depressions of this margin the capsule is thickened, and at the lowest point the thickened capsule sweeps down into the substance of the gland, and following the distribution of the portal system

invades the whole organ. It envelops single acini and groups of acini, but manifesting no tendency to invade the lobule except at the surface of the liver, where the process seems to have been more active and of longer standing. There is also a moderate increase of connective tissue about the intra-lobular veins. The liver-cells are everywhere in a condition of fatty infiltration, uniformly from periphery to centre; nuclei are distinct; cell-bodies are finely granular, outlines usually well defined.

In the interior of the liver the connective tissue is well organized. Near the upper surface there is a free sprinkling of lymphoid cells upon a background of organized connective tissue. The veins and arteries are not obliterated, and there is no increase of bile canaliculi remarked by some observers. In the spleen there is a slight increase of connective tissue. This, however, is difficult to maintain; it is on the border-lands between a normal and pathological condition.

After the autopsy the records of the institution were searched, and the following additional information gained: The child entered the house when one day old. "Condition fair." "Condition," uniformly reported, "good" till May, 1882, when she was adopted by French parents, with whom she lived four or five months, and was returned in good condition. This was about two months before death. There is no history of syphilis, and in this case the records are unusually satisfactory. The child's health was always good. She was regarded a very "clean child," bright, active, and attractive. During her stay with the French parents there is no reason to think she was abused or indulged in irritating food or drink.

Remarks.—"In the 'Transactions of the Pathological Society of London' for 1876 I find three cases of cirrhosis of the liver in children. Dr. T. Griffiths reports a case. He remarks, in conclusion, 'This is an excellent specimen of a cirrhotic liver from a child ten years of age, without any evidence whatever, on the most careful and satisfactory inquiry, of its having been produced by the use of alcoholic drink or irritating food of any kind. Neither is there a particle of evidence of hereditary syphilis, of previous history of rickets, diseased bone, or chronic abscess.'

"Dr. W. Cayley reports a case of a female child, six years of age. No history of syphilis or drink. No illness since whooping-cough at nine months of age. He found changes akin to those in the liver in brain, heart, stomach, spleen, and kidneys.

"Murchison reports a case in a boy nine years of age. 'After the boy's death it was ascertained that his father kept a low public-house, and that the boy had been in the habit of drinking a good deal of wine and water, especially between meals. While in hospital he took stimulants with a readiness quite unusual in children.'

"He concludes: 'So far as my experience goes, I have never met with a typical example of hob-nailed liver (as distinguished from other forms of contracted liver) after death, at any age, in which there could be made out a clear history of moderation in the use of alcohol. In early life it is not improbable the activity of the liver may render it more liable to suffer from alcohol or other irritating ingesta than adults.'

"In the above cases the children suffered from the ordinary symptoms of cirrhosis, and all were tapped several times.

"Dr. J. Wickham Legg ('St. Bartholomew's Hospital Reports,' vol. xiii., 1877, page 148), in a very able *résumé*, reports two cases of his own—one in an infant of seventeen months. The prominent symptom during life was purging, and just before death symptoms of tubercular meningitis. Death was due to the latter. He remarks: 'No symptom to suggest a special attention to the liver was present.'

"Another was a boy twelve years of age, whose symptoms suggested typhoid fever or tuberculosis, and yet neither tubercle nor ulcer of Peyer's patches was found.

'In either case,' he adds, 'almost superhuman sagacity would have been needed for the diagnosis to have been made aright.' On examination, the livers were found to be in condition of ordinary cirrhosis, very similar to that of adults, 'bands of connective tissue about the acini; connective tissue studded with lymphatic cells.' Liver-cells granular in one case, fatty in the other.

"Dr. Samuel Wilks reports a case of syphilitic cirrhosis in a child one month old. Surface of liver was smooth, resembling fibrous tumor; secreting cells were unchanged.

"Dr. Frederick Taylor reports ('Transactions of the Pathological Society of London,' 1880) a case of a child five years of age. No evidence in life or at post-mortem examination of syphilis; evidence as to alcohol incomplete. 'On one occasion (the child) admitted he knew the difference between brandy and gin and liked them, and that he had often had them at night.'

"In the 'Transactions of the Pathological Society of London,' for 1881, is reported a case of a boy nine years of age with congenital hydrocele, and later ascites. No history of syphilis in parents. The child was often sent to bring the ale for father and mother, and it is said he often took a 'sip of ale.' He says: 'The history of morning sickness—the splenic engorgement, the nausea, appearance of the liver, are in favor of alcohol being the cause.' Of nineteen cases mentioned by Legg, ten were girls and nine boys. Of fifteen cases the ages were between seven and thirteen years, three between five and six years, and one of seventeen months. He quotes F. Weber for a case of cirrhosis in a stillborn child (no mention of syphilis in this case).

"As to the causes of cirrhosis of the liver in children: 1. French and German authors agree with Murchison that before and during the first dentition cirrhosis other than syphilitic is rare. 2. After the first dentition the most frequent cause is undoubtedly the use of alcohol; irritating food may cause it (Murchison and Niemeyer). 3. Legg says: 'It seems to me a highly probable conclusion that cirrhosis may arise independently of excess in alcohol.' In his twelve-year-old case the symptoms were of a grave general disorder, high temperature (103 to 104°) and delirium. There was no jaundice, no ascites. This case showed cirrhosis of liver, pleurisy, and parenchymatous nephritis. Cayley's case showed changes in brain, heart, stomach, spleen, and kidneys, of similar nature.

"Hillier reports a case of cirrhosis in which were also pericarditis and pleurisy. He suggests that 'cirrhosis may be the expression of some general disease of the lymphatic tissue throughout the body.'

"Dr. Hayden, in the *Dublin Journal of Medical Science*, reports a case of cirrhosis in a boy of fourteen years, complicated with 'cirrhosis' of kidneys, with pleurisy and pericarditis.

"Dr. Thomas Olivier in the *British Medical Journal*, reports a case in a female infant three months old. Parents both temperate; no history of syphilis. He adds: 'Syphilis will not, however, explain all cases of cirrhosis of the liver, even in the young.'

"One author, already quoted, says: 'The view that cirrhosis is due solely to an intemperate use of liquors, seems hard to sustain, when it is considered that not only domestic animals but wild animals suffer from cirrhosis.'

"Briefly to summarize: 1, The anatomical appearances are in no way distinguishable from the cirrhosis of adults; 2, from birth to two and one-half to three years in cases of cirrhosis of the liver the presumption is in favor of syphilitic origin; 3, later than three years of alcoholic origin; 4, in many cases it seems fair to regard it as a general disease."

DR. J. C. PETERS said the records of the Society showed that specimens of cirrhosis of the liver had been presented which were removed from the bodies of children ten, twelve, and fourteen years of age; the majority of them were females, and in none was there a history of excess in the use of alcoholic drinks.

DR. HEINEMAN remarked, in commenting upon the admirable *résumé* of Dr. Northrup, that the explanation suggested by some as an etiological factor in cirrhosis of irritative articles of diet, as well as of drink (alcohol), was perfectly rational. Intestinal dyspepsia was a common enough disease in young children and adults, and there was no reason why repeated and long-continued irritation of the duodenum, accompanied as it was often by functional liver derangement might not in some cases be followed by structural lesion.

Functional disorders were, with the light of physiological chemistry, beginning to be considered as manifestations of real cell changes, which it is true were not always recognizable after death, just as were congestion and even slight catarrhal inflammation not always to be recognized post mortem. The fact stated by Dr. Northrup, that it is only in children over three years of age that cirrhosis is found independent of syphilitic or alcoholic origin, possibly helped this theory, since, as was just stated, it was at and after this age that dyspepsia became so common an affection.

DR. J. LEWIS SMITH remarked that in the *Revue de Médecine* for July and October last, Dr. Lancereaux described three varieties of cirrhosis, the alcoholic, syphilitic, and malarial. In the syphilitic the liver is deeply furrowed. It is not attended by ascites or icterus. In the malarial variety the liver is firm and it presents a slightly granular surface. In alcoholic cirrhosis the liver is contracted, hard, and nodulated, or it is somewhat enlarged, with smooth or granular surface, and the microscopic examination shows hyperplasia of the connective tissue, and fatty degeneration of the gland-cells.

In young children we can exclude alcoholism as a cause of cirrhosis, and if there be no history of inherited syphilis, may we not in these cases of obscure etiology regard malaria as the cause? Certainly in and about New York malaria is an important and common factor in the causation of disease. An abstract of Lancereaux's paper appears in the *London Medical Record* for March 15th.

CONGENITAL SYPHILIS—SECONDARY TUBERCULOSIS.

DR. L. E. HOLT presented the lungs, spleen, and portion of liver and kidneys removed from a boy four and a half years of age, who died on April 5th, at the Sixty-third Street Institution, and for the specimens he was indebted to the courtesy of Dr. Ripley. The boy first came under Dr. Holt's observation on February 16th of this year, with the following history: His family history was negative; he was one of four children: two were healthy, one died early in infancy. This child, when four weeks old had an eruption on the skin and also had snuffles, was backward in its development, and was unable to walk alone until it was three years old. It had suffered from cough, had had irregular fever, no sweating at night, had a chronic nasal catarrh, abdominal pain, and constipation. The child was feeble, its face pinched, and it had a fetid discharge from the nostrils, which had also excoriated the upper lip. The cervical glands were considerably enlarged on both sides, and there was also enlargement of the jugular veins. The upper incisors were absent entirely; the lower incisors were in a condition of caries. The chest was decidedly rachitic, and the extremities of the long bones were enlarged. On the right index finger was an onychia which had existed two or three weeks, and the left great toe was the seat of dactylitis. The abdomen was greatly distended, and the abdominal veins were enlarged and tortuous, but there was no fluid in the peritoneal cavity. The liver was considerably enlarged, as also was the spleen. The temperature was 103° F. No satisfactory examination of the lungs could be obtained. The child was referred to Dr. Ripley at the Polyclinic, who found consolidation at both apices, general bronchitis, and on the right side behind, evidence of a small cavity about the size of a walnut. The patient was placed upon the mixed treatment, with the addition of cod-liver oil, iron, and tonics, which were

kept up about one month without any improvement. The febrile movement continued, the temperature once reached 103.5° F. When Dr. Holt saw the child last, on March 23d, all the symptoms were aggravated. There was, however, no fluid in the abdominal cavity. Commencing onychia was seen upon every finger of the left hand, and upon the fingers of the right hand. The child continued to have fever, the temperature ranging from 100° to 101° F. with considerable pain and tenderness in the region of the liver. Physical signs were more pronounced on the right side of the chest, and later the evidence of a small cavity was found on the left side anteriorly. Examination of the urine was negative, except once, when a trace of albumen was found. There were no head symptoms at any time. Toward the termination of the case the patient had diarrhoea, but had no vomiting at any time. Death occurred by slow asthenia.

At the autopsy small cavities were found in the apices of both lungs, with surrounding consolidation. There were pleuritic adhesions on both sides. The heart was normal, also the pericardium. The omentum was adherent, but it contained no tubercles, nor were tubercles seen on the surface of the intestines. The liver was enlarged and contained yellowish nodules, varying in size from that of a pea to a pin's head, and situated about the bile-ducts. Miliary tubercles could be seen sparsely scattered over the surface of the organ. The spleen was considerably enlarged, and firm and adherent to the surrounding organs. Scattered through the tissue of the organ were very numerous nodules, which resembled those seen in the liver, very firm and hard, but there were no tubercles seen upon the surface of the organ. The kidneys showed nothing abnormal to the naked eye. It was impossible to say what the nature of the nodules in the liver and spleen was without a microscopical examination.

The case was interesting, because it showed—first, quite a clear history of congenital syphilis, and, second, pretty conclusive evidence of the development of tuberculosis which seemed to have come on as secondary to the syphilis.

The specimens were referred to the Committee on Microscopy.

CARCINOMA OF THE BREAST.

DR. L. H. SAYRE presented a mammary cancer with axillary glands, removed from a patient fifty-three years of age. There was no history of cancer in the family. Six weeks ago a lump appeared in the left breast, which gradually increased in size, and two weeks ago he removed it by making an elliptical incision. The operation was performed under the antiseptic spray. The wound had entirely healed.

AMPUTATION AT THE KNEE.

DR. SAYRE also presented a leg removed from a female patient sixteen years of age, who had a fair family history. When eighteen months old she was attacked with disease of the knee-joint, which continued for about three years, and resulted in complete bony ankylosis with the usual deformity of flexion, subluxation, and rotation outward. The leg was flexed at a right angle with the thigh. The patella was completely fused, and the articular surfaces of the tibia and femur were also completely ankylosed. It was decided to amputate in preference to attempt *brisement forcé*, for the reason that the ankylosis was so firm it would probably be impossible to break it up; but if able to break it up, there would be great danger of rupturing the popliteal artery. In the event, however, of being able to avoid that accident, the limb would probably be useless for the reason that the joint surfaces had probably become destroyed. Amputation was preferred to Buck's operation of removing a wedge-shaped section, for the reason that the limb was already three and a half inches shorter than its fellow, and the patient has not yet attained her growth. Con-

sequently exceedingly high support for the foot would be necessary, which would give more inconvenience than would an artificial limb. Amputation was selected, and was performed by making a modification of Stephen Smith's operation. In this case it was found impossible to disarticulate the joint, and it was therefore necessary to saw through the head of the tibia. The operation was performed under the spray, the wound was closed with sutures, and an antiseptic dressing applied. Three days after the operation the dressings were removed, the sutures taken out. There was no secretion of pus, the temperature had not been elevated above $100\frac{1}{4}^{\circ}$ F., and the pulse had not risen above 102.

DR. GARRISH said that Dr. Valentine Mott made it a rule never to operate for removal of a cancer until the integument became ulcerated.

DR. GIBNEY remarked that he had met with numbers of limbless people who came to the hospital with irritable stumps and broken artificial limbs, and in many cases it would seem that resection of some kind in adult life, at least, would have been a better mode of procedure. He therefore asked Dr. Sayre if he would have performed amputation had the patient obtained her entire growth?

DR. SAYRE replied that he thought the artificial limb would be more advantageous to the patient than a high shoe or other support.

DR. WYETH thought that an osteotomy would have been less dangerous than amputation, although amputation is not, as a rule under such circumstance, a dangerous operation. He thought that, on the whole, if an osteotomy had been accomplished successfully, and the limb placed in the desired position, it would have been better, so far as utility is concerned, than an artificial limb. He believed that he should have tried osteotomy, straightened out the limb, and endeavored to utilize the leg and foot. Again, if amputation had been necessitated, he thought it was recognized as more favorable to utilize the normal tissues which have been accustomed to pressure, and therefore to save some of the tissue below the knee to form a basis for the support of the artificial limb.

DR. SAYRE remarked that the cicatrix in this case was entirely behind and in the popliteal region, and that its lowest part was an inch and a half above the end of the stump.

DR. GIBNEY asked concerning the per cent. of mortality in knee-joint amputation and resection.

DR. WYETH replied that twenty-five per cent. of the cases of resection of the knee-joint terminate fatally; that the mortality after amputations in which the wounds were sewed up was twice as great as in those cases in which the amputation was left open. He then referred to the fact that at one time he looked over the history of several hundred cases in Bellevue Hospital, and found that in every other amputation the patient died. Dr. Dennis reported fourteen cases in which the operation was performed by the late Prof. James R. Wood, and all of the patients recovered. All the stumps were treated openly. He knew of over one hundred cases which were treated in the same way, and in none of them did septicæmia or pyæmia cause death, and the rate of mortality was far below that of amputations treated by the closed method. Recently he had made seven consecutive amputations. The wounds were treated openly, and all the patients recovered. Amputation at the knee-joint for disease is fatal in about one in seven cases.

EMBOLIC PNEUMONIA—THROMBOSIS OF THE UMBILICAL VEIN.

DR. J. LEWIS SMITH presented the lungs removed from an infant which died at the age of fifteen days. There was nothing unusual in the condition of the child until it was about one week old. It became feverish and fretful, and on examining carefully for the cause of this trouble evidence was found of inflammation at four

different localities under the skin, circumscribed cellulitis, little nodules about half an inch to an inch in diameter. The child began to fail soon after, and died at the age mentioned. At the autopsy there was found in the lower lobe of the left lung on the posterior aspect, a small nodule of pneumonic consolidation. On opening this its interior presented a grayish appearance, of the wedge-shape, characteristic of embolic pneumonia. Around this wedge-shaped portion of consolidation the lung presented a hyperæmic appearance, as is common in this form of pulmonary inflammation. It was believed that there would be found somewhere in the body a thrombus, and further examination revealed what seemed to be the true source of the pulmonary disease and the cellulitis, namely—a softened thrombus in the umbilical vein. This vein contained a purulent looking liquid which under the microscope was found to be simply softened thrombic material to the amount of five or six drops. The question might be asked why, if this was the source of the embolic pneumonia, do not embolic inflammations occur more frequently in the newborn. The clot in the umbilical vein evidently remains undisturbed *in situ*, under ordinary circumstances, since there is no propulsive power acting upon a thrombus in this vein, as is the case in the systemic veins when thrombi form. It is usually, no doubt, absorbed within the vein, or it enters the circulation gradually and in a different state so as to do no harm. But we can easily understand how, by rough handling of the child, especially by sudden and firm pressure on the abdomen, as in tossing, a portion of the thrombus might enter the circulation and produce such inflammations as were present in this case. Some years ago he presented to the Pathological Society specimens from a young infant, showing numerous abscesses. The cause may have been the same as in this patient, but it was not at the time suspected.

DR. JOHN C. PETERS then made a preliminary report on scarlet fever in horses, after which the Society went into executive session.

THE CAUSE AND CURE OF CHOLERA INFANTUM.—Dr. A. E. Walker, of Mount Liberty, O., sends us some judicious criticisms upon "Henoch's Lecture on Cholera Infantum," published in "Wood's Library of Standard Medical Authors, for 1882." Dr. Walker believes that high temperature is not given its proper importance as a cause of disease. "One other fault I find in his lecture is that his cases of cholera infantum appear to have assumed a chronic form (figuratively speaking). He says that when we are called to see a patient suffering an attack of cholera infantum on the second or third day of the disease, we can administer such remedies as he indicates. Now, in this part of the world (it may be entirely different in Berlin) a physician is scarcely ever called upon the second or third day after the attack has begun, unless it is for the mother of the babe who is suffering from nervous shock caused by the sudden death of her child. As I understand cholera infantum, it is very sudden in its onset and the majority of cases die within thirty-six hours if left to the curative efforts of nature."

Dr. Walker thinks that Henoch's treatment would be valueless in a vast majority of cases. He recommends, in the place of it, the plan adopted by Professors D. N. Kinsman and Pooley, of Columbus, O. These gentlemen commend injections of ice-water, cold compresses to abdomen, and in addition to this Dr. Pooley advises the use of sub. nit. bismuth in the following doses: he takes enough bismuth to make a tolerable thick cream, using aqua dist. as the vehicle; of this he gives from one-half to one teaspoonful about every four hours until choleric discharges cease.

Dr. Walker writes: "This plan of treatment, I believe, is destined to become the treatment *par excellence* in cases of cholera infantum."

Correspondence.

MEDICAL CONTROVERSY AND THE NEWS-PAPERS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: One of the evils following the effort of a part of our profession to change our Code, is the tendency of the discussion to be diverted into the newspapers. Is it wise to yield to this tendency? Both Codes condemn it. The first sentence of the New Code says: "It is derogatory to the dignity and to the interests of the profession for physicians to permit their opinions on medical questions to appear in the newspapers." If any physician, prompted by a spirit of individual liberty, allows himself to disregard this teaching, he ought, certainly, for the dignity and interests of the profession, to be very careful not to overstep the bounds of truth, while purporting to narrate simple facts. Dr. Abram Jacobi—than whom few cultivators of medical science, or disciples of humanity, have reached a higher eminence in the profession—has, unfortunately, fallen into a mistake of this kind, in his letter to the German physicians, published in the *New York Tribune* for May 3, 1883. He says: "The New Code was confirmed, after long discussion, by an increased majority, at the meeting of 1883." Of course the facts are the reverse of this. In 1882 the vote stood fifty-two to eighteen; majority, *thirty-four*. In 1883 the vote was one hundred and five to ninety-nine; majority, *six*.

Doubtless, friends of the American Code, and at the same time friends of Dr. Jacobi, may find some other mistakes, or perverted influence, in this letter, so conspicuously published. It may not be best to descend to minor criticism in matters of this kind; but, plainly, a friendly critic is justified in calling attention to an error of this magnitude and import, and in respectfully requesting the author to have it publicly corrected.

T. H. SQUIRE, M.D.

ELMIRA, N. Y., May 5, 1883.

DOES THE RETENTION OF DEAD TEETH IN THE JAWS EXERT AN UNFAVORABLE INFLUENCE ON HEALTH?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The report of the proceedings of the April meeting of the Practitioners' Society in THE RECORD of May 5th, in which the discussion of my paper on "Earache in Children" appears, omits some remarks that were made respecting the retention of pulpless or "dead" teeth in the jaws. I should not desire the publicity afforded by the columns of THE RECORD for a special communication regarding this matter, were it not to draw greater attention to the probable bad effect on health from keeping "dead" permanent teeth indefinitely in the mouth. Every one is naturally reluctant to part with any of their teeth, however greatly impaired they may be, so long as they can be made to serve a useful purpose, unless, indeed, toothache cannot be prevented; and I am, moreover, quite well aware that many practitioners are not unmindful of their patients' interests in this regard, and that, in the treatment of diseases seeming to be influenced by dental irritation, the management of the teeth is very properly relegated to the more competent care of competent dentists. But we ourselves very often encounter dental disturbances in our patients, the harmfulness of which is not suspected by them, so long as pain is absent, yet we very well know from experience that they constitute important causative factors in certain diseases. Thus, when it is found that teeth have, in consequence of death of the pulp, been deprived of an important source of nutrition—the only remaining source of nourishment being through the periosteal connection—their vitality is frequently so much impaired that their

entire separation from the jaw is usually only a question of time. If it is sought to retain these defective teeth by means of fillings, we are met by the fact that this cannot always be effectually done, inasmuch as the death of the parts, with greater or less speed, still goes on, and the products of pathological processes, small though they may be, cannot be considered as entirely free from danger to the patient when absorbed. The presence of fillings in these cases is an effectual barrier to the natural escape of deleterious products, unless, indeed, alveolar abscesses form. The "dead" tooth may be in a certain sense regarded as a foreign body, and the occurrence of periostitis, as is well known, may give rise to greater or less irritation; thus may either an acute or a chronic process be set up, the former causing pain or alveolar abscesses, or both, while the latter may continue almost indefinitely with, for the most part, scarcely any pain.

But these appliances are not always intended to serve the purpose of stopping cavities only, for mechanical skill, in a certain branch of dentistry, has made it possible for the operator to permanently attach gold or amalgam mounts to teeth, the crowns of which have yielded to the ravages of caries, in such a manner as to offer very useful substitutes. These metallic substances, some of which are very large, are not, I fear, always harmless when continuously worn in the mouth.

Now, while I am very far from recommending that all pulpless ("dead") teeth should be removed, yet I believe that in many instances they cannot be retained without injury to the patient. I am quite sure that I have seen many recoveries in my aural practice quickly follow the removal of a defective tooth. I shall be glad if others who have had opportunities for observation would contribute their experience to the literature of this subject.

Yours sincerely,

SAMUEL SEXTON, M.D.

New York, May 7, 1883.

New Instruments.

A NEW INSTRUMENT FOR LIGATING THE UTERINE ARTERY.

By CLINTON CUSHING, M.D.,

PROFESSOR OF GYNECOLOGY, COOPER MEDICAL COLLEGE, SAN FRANCISCO, CAL.

In September, 1881, I essayed the removal of the entire uterus through the vagina on account of epithelioma of the cervix. At the outset of the operation I undertook to ligate the uterine artery upon either side of the cervix, and between the cervix and the ureter, just above the vaginal vault. I used for this purpose a strong curved needle and a heavy needle forceps, and was enabled, after several failures and much difficulty, to pass a ligature above the artery, and thus ligate it before any incisions were made in the tissue around the cervix. The operation was then carried out according to the original plan, without the loss of blood, and the operation was followed by recovery.

In looking over the literature of pelvic surgery, I was surprised to find no mention made of any plan by which the uterine artery might be ligated, whether for the control of hemorrhage or for ablation of the uterus.

I at once began a series of experiments upon the cadaver, with a view of determining some method best suited to ligating the uterine artery from the vagina, and without opening the abdomen. After making several dissections I became convinced that the only point that the artery could be reached without endangering the ureter was midway between the body of the uterus and the ureter.

To understand clearly what I am about to say, it must be remembered that the uterine artery furnishes at least four-fifths of the blood supply to the uterus; that it arises

from the internal iliac artery at the point of its bifurcation, and passes inward along the lower edge of the broad ligament, and reaches the uterus just above the cervico-vaginal junction, where it sends off the circular artery of the cervix, and then passes upward along the side of the uterine body, sending off numerous tortuous branches to that structure, and finally anastomosing with the ovarian artery, an exceedingly small vessel.

The uterine artery is about the size of the radial, and can be felt with the finger through the roof of the vagina in thin subjects, its pulsations being clearly perceptible. The ureter passes over the brim of the pelvis about one inch to the side of the promontory of the sacrum, and extends downward and slightly inward beneath the pelvic peritoneum, just external to the utero-saral ligaments, reaching the connective tissue of the broad ligaments about three-fourths of an inch laterally from the cervix, where it passes behind and in close juxtaposition to the uterine artery. The ureter then passes forward between the bladder and vagina, opening into the bladder about one inch in front and below the cervix uteri. In studying Savage's plates, one is led to suppose that the ureter is

nearer the cervix than is really the case, as can be easily proven by passing a small flexible bougie through the ureter, from the brim of the pelvis into the bladder, and then studying the parts *in situ*.

The accompanying cut represents an instrument that I have devised for the purpose of passing a ligature around the uterine artery from the vagina without endangering the ureter.

As will be seen, each blade of the instrument consists of a small canula, curved at its terminal end, so that when the blades are united and closed they form a half circle, and the two canulas when joined represent a closed tube from handle to handle. The end of each canula is furnished with a trocar point.

The method of using the instrument is as follows: Place the patient on the left side and introduce a large-sized Sims' speculum; seize the cervix with a strong vulsellum, draw it down slightly, and steady it; now take one of the blades and pass it through the roof of the vagina a third of an inch to the side of the cervix, and a third of an inch back of the median line running from the cervix to the side of the pelvis; pass the canula into the tissue of the broad ligament until the opening *a* of the canula has entered one inch, keeping the point of the trocar within a half inch of the body of the uterus. Now introduce the other blade in front of the cervix and to the side in a similar manner, and close and lock the handles of the instrument, and the curved ends of the canulas come together in the connective tissue of the broad ligament above the uterine artery, and between the ureter and the uterine body. Now take a piece of steel wire, No. 23 gauge, made quite sharp at one end, and with a loop at the other for the attachment of a ligature, and pass it around through the canula and draw the ligature into its place. The sharp end of the wire pierces any portion of the connective tissue that may become engaged between the ends of the canulas. The blades are now unlocked and removed separately, and the ligature is left in their track, and by tying it firmly the artery is perfectly controlled, and much the larger part of the blood supply to the uterus is cut off.

The cut represented is one-half the size of the original instrument.

It has occurred to me that by ligating these arteries in cases of uterine fibroids, that their growth would be checked and atrophy follow, and I expect at some future time to report the results of the experiment. The ligation of these arteries, as the first step, renders the ablation of the entire uterus comparatively easy to those who are practically familiar with this branch of surgery. Whatever the disease or operation that causes serious uterine hemorrhage, this method of procedure may prove of service.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 28, 1883, to May 5, 1883.

BAILY, JOSEPH C., Major and Surgeon. To be relieved from duty in the Department of California and assigned to duty in the Department of Texas. S. O. 102, par. 12, A. G. O., May 3, 1883.

TILTON, HENRY R., Major and Surgeon. To be relieved from duty in the Department of the Missouri and assigned to duty in the Department of the East. S. O. 102, par. 13, A. G. O., May 3, 1883.

CRAMPTON, LOUIS W., Captain and Assistant Surgeon, now awaiting orders. To proceed without delay to Fort Wayne, Mich., and report to the commanding officer for duty at that post. S. O. 73, par. 2, Department of the East, April 30, 1883.

PAULDING, HOLMES O., Captain and Assistant Surgeon. To be relieved from duty at Fort Sidney, Neb., and assigned to duty at Fort Douglas, Utah. S. O. 42, par. 1, Department of the Platte, April 25, 1883.

PERLEY, HARRY O., Captain and Assistant Surgeon. To be relieved from duty in the Department of the East and assigned to duty in the Department of Dakota. S. O. 102, par. 14, A. G. O., May 3, 1883.

SPENCER, WM. G., Captain and Assistant Surgeon, now awaiting orders. Assigned to duty in the Department of the East. S. O. 102, par. 12, A. G. O., May 3, 1883.

WORTHINGTON, JAMES C., Captain and Assistant Surgeon. To be relieved from duty in the Department of the East and assigned to duty in the Department of the Missouri. S. O. 102, par. 14, A. G. O., May 3, 1883.

BIART, VICTOR, First Lieutenant and Assistant Surgeon. To be relieved from duty in the Department of the Missouri and assigned to duty in the Department of Dakota. S. O. 102, par. 13, A. G. O., May 3, 1883.

MACAULEY, CASTER N. B., First Lieutenant and Assistant Surgeon. To be relieved from duty in the Department of the East, and assigned to duty in the Department of Dakota. S. O. 102, par. 12, A. G. O., May 3, 1883.

STRONG, NORTON, First Lieutenant and Assistant Surgeon. Upon expiration of leave of absence, to be assigned to duty at Fort Thornburgh, Utah. S. O. 42, par. 2, Department of the Platte, April 25, 1883.

BYRNE, CHARLES B., Captain and Assistant Surgeon. To be relieved from duty in the Department of the South and assigned to duty in the Department of the Missouri. S. O. 102, par. 12, A. G. O., May 3, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending May 5, 1883.

LAW, H. L., Passed Assistant Surgeon. Detached from the Navy Yard, League Island, Pa., on 10th inst. and ordered to the Yantic.

HARVEY, H. P., Passed Assistant Surgeon. Detached from the Yantic on reporting of relief and ordered to Naval Hospital, Chelsea, Mass.

SENIOR, WM. J., Surgeon. Ordered as member of a board at Naval Academy.

MCCLEURG, W. A., Passed Assistant Surgeon. Detached from the Naval Academy on the 15th inst. and ordered to the Dale.

DIEHL, OLIVER C., Assistant Surgeon. Detached from the Naval Academy and ordered to the Constellation.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending May 8, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
May 1, 1883.....	13	7	153	4	167	54	2	0
May 8, 1883.....	5	8	166	9	170	44	1	0
<i>Deaths.</i>								
May 1, 1883.....	1	3	23	4	22	17	1	0
May 8, 1883.....	0	5	28	9	24	25	2	0

The total mortality for the week ending May 5, 1883, was 703, of which 91 were from pneumonia.

WOUNDS OF THE ABDOMEN AND ABDOMINAL SURGERY.—Dr. S. D. Seelye opened a discussion upon the above subject before the Medical and Surgical Society of Montgomery County, Ala., March 3d. Dr. Seelye described the relative fatality of wounds of the different viscera. He said: "Wounds of the stomach give the highest rate of mortality. Dr. George A. Otis, in the 'Medical and Surgical History of the War,' calculates, after careful sifting of all the literature on the subject which his great facilities could give him access to, that the mortality from wounds from this viscus is nearer ninety-nine per cent. than Percy's estimate, which was seventy-five per cent. Comparatively uncomplicated wounds of the liver show a mortality of sixty-six per cent. Without giving the percentage of mortality in wounds of the kidneys, it is enough to say that they are not among the most fatal of such wounds, provided that only one is injured and free drainage can be maintained. Wounds of the bladder show a favorable result as compared with wounds of other viscera. Wounds of the intestines, next to those of the stomach, are the most fatal. Yet these latter present differences according to location of wound. Injuries to the ascending and descending colon are less fatal than those of other portions of the bowels. This we might expect when we remember that posteriorly these portions are, through a part of their course, uncovered by peritoneum on their posterior surface." Dr. Seelye's conclusions were expressed by the following: "Is it enough that we examine the little hole made by the bullet, and, as Abernethy said nature does in these cases, 'Shakes her head and leaves the patient to his hopeless fate?' Is not aggressive surgery the true conservatism in these cases? We doubt not the time will soon be when the surgeon will open up the abdomen, examine the nature of the injuries, tie bleeding vessels, sew up wounded gut, clean out extravasated matter, excise spleen, if necessary, and do anything and everything to help nature repair the injury, as we do in external wounds." The views of the speaker were concurred in by most of those who took part in the discussion.

THE SALE OF PATENT MEDICINES IN JAPAN.—It is stated in the first report of the Central Sanitary Bureau of Japan, just issued, that the Government has established a public laboratory for the analysis of chemicals and patent medicines. The proprietors of patent medicines are bound to present a sample, with the names and proportion of the ingredients, directions for its use, and explanations of its supposed efficacy. During the year there were no fewer than 11,904 applicants for license to prepare and sell 148,091 patent and secret medicines. Permission for the preparation and sale of 58,638 different kinds was granted, 8,592 were prohibited, 9,918 were ordered to be discontinued, and 70,943 remained still to be reported on. The majority of those which were authorized to be sold were of no efficacy, and but few were really remedial agents. But the sale of these was not prohibited, as they were not dangerous to the health of the people. If similar regulations were put in force in this country, it is probable that the sale of several patent medicines would be put a stop to.

OLD FOGYISM.—The profession in America labors under another drawback which will hamper it for some time to come, namely fogyism, within its circles and outside public opinion, which is too often prone, as far as medicine is concerned, to consider only one phase of the subject and that the worst. What an outcry would go up from some of our teachers themselves and the public generally if a patient were stripped, especially a woman, before a class, for the purpose of studying a skin affection! Yet that is the way that patients are handled here. And if they were not so examined, in many instances it would be impossible to make out a correct diagnosis, as is daily exemplified here.—*Vienna cor. of The Quinologist.*

THE ANCIENT OPERATION FOR CIRCUMCISION AMONG THE JEWS.—Dr. S. Wiltshire (*Medical Press and Circular*) thus describes this operation: "The operation is always performed on the eighth day after birth. Two seats are prepared in the morning with silken cushions, one for the godfather, who holds the child, the other, as they say, for the Prophet Elias, whom they suppose to assist invisibly. The person who is to circumcise brings the necessary appliances—the razor, styptics, linen fillet, oil of roses, to which some add a shellful of sand to catch the blood, and put the prepuce in when removed. A Psalm is sung till the godmother brings the child, attended with a crowd of women, and delivers it to the godfather, none of them entering the door; the godfather, being seated, sits the child on his lap, then the Mohel, or circumciser, taking the razor and preparing the child for the operation, says with a loud voice: Blessed be Thou, O Lord, who has enjoined us circumcision. And on so saying cuts off the thick skin of the prepuce, and with his finger-nails tears off another finer skin remaining, sucking the blood by putting the penis into his mouth for two or three seconds and then spitting out into a glass of wine. Then he lays dragon's-blood on the wound with powder of coral and other styptics to arrest bleeding, and staunch any blood that might flow. Over all he places a fillet or compress saturated in oil of roses, and then binds up the whole; that being done, he takes a glass of wine, and blessing it, adds another benediction for the child."

THE SEQUELÆ OF TRACHEOTOMY.—Mr. Ross read a paper on "Sequelæ of Tracheotomy Occurring after Closure of the Tracheal Wound," before the Edinburgh Medico-Chirurgical Society recently, in which he pointed out that some important lesions tending to cause tracheal stenosis may occur as a result of the operation of tracheotomy, without manifesting their presence till some time after the tracheal wound had healed. Notes were given of the case of a young woman, who had undergone the operation at the age of eighteen months for the removal of a hook from the larynx. She now suffered

from occasional attacks of dyspnoea. The laryngoscope showed a catarrhal condition of the mucous membrane, with a great want of development of the vocal cords. At the bottom of the internal cicatrix, there was what appeared to be a diaphragmatic membranous stricture, which occluded more than one-half of the tracheal lumen—a condition which has been described once or twice as occurring after cut throat, but not hitherto, so far as is known, after the longitudinal tracheal wound. Mr. Ross also referred to the interesting question which has been stirring the minds of French surgeons recently: "What becomes of children who have successfully undergone the operation of tracheotomy?" Very few adults are seen with the tracheal scar, in whom the operation has been done in childhood.—*N. E. Medical Monthly.*

THE ATTACKS AGAINST NEW YORK PHYSICIANS.—I do not write to defend our specialists, however, who can, no doubt, take care of themselves; but only for fair treatment toward them and toward the profession of New York. It seems to me that there is no call for so much violent feeling and vituperative language. The profession is not going to be destroyed or disintegrated, as has been intimated. I do not think that we are victims of moral decay. I find it perfectly safe to mingle freely with my neighbors. The view in this city, I think, is, that by removing a restriction that had been a dead letter, we have placed ourselves in a better light before the world; have removed an affront and a stimulus to homœopathic progress, and have only set aside a technical morality which infringed on the individual's rights without elevating him in return. We believe that the true work for professional elevation lies in securing a higher educational standard, better trained minds, a more scientific spirit, and a greater technical skill in our midst. We believe that this work can be better done without the embarrassment and reproach caused by the restrictive Code. We believe that skilled and learned physicians, obedient to the laws of God and the dictates of common morality, are what the profession needs. Why cannot the profession at large admit that we too in New York may, perhaps, be honest and earnest in our views. And is it not barely possible that the American Medical Association has been a little hasty in cutting off from its membership a State like New York, because of an honest disagreement in by-laws?—*Cor. Chicago Medical Journal and Examiner.*

A LOUISVILLE SUIT, brought by Dr. Vance of that city, for recovery of fees for professional services, has excited considerable interest. Some four or five medical men in that ethical centre testified that Dr. Vance had performed an improper operation. The jury found in favor of the plaintiff.

DR. F. W. PUTNAM, of Binghamton, N. Y., writes us a letter regarding the new Code, in which he makes the point that it forbids regular physicians to advertise, thus tying their hands, yet places the irregulars who do advertise on a level with the regular profession.

The homœopaths have a code which is nearly identical with that of the American Medical Association. It ought to keep them from advertising.

COTTAGE HOSPITALS.—Two hundred and fifty cottage hospitals are now in successful operation in England, relieving about fifty thousand patients annually, who contribute to the hospital at least one-sixth the cost of their maintenance. If this system could be generally introduced into this country, a large class would be provided with hospital accommodations who are now deprived of their advantages, and many of whom would be willing to pay a small sum weekly for the medical care and nursing thus provided. A large outlay is not required, for the necessary building need not be expensive. In England, the average cost of cottage hospitals, having a capacity of about eight beds, is from \$4,000 to \$6,000 each. In the experience of Dr. L. W. Baker, a capacity of twenty-five

beds for children, \$5,000 will about cover the expense of land and building; of course the cost of construction will vary with the location, but there is surely no town of ten thousand inhabitants and upward too poor to establish and maintain one of these small institutions.

MORTALITY IN NEW YORK DURING THE PRESENT YEAR.—Dr. F. A. Burrall writes to correct what he, by a misunderstanding, considers an error in our editorial on "Pneumonia in New York" (MEDICAL RECORD, March 31st). We stated that for January and February the weekly mortality from *pneumonia*, not the total mortality, was greater than in 1882. The context will show this.

THE ADVERTISEMENT OF QUACK MEDICINES IN RELIGIOUS JOURNALS.—Dr. E. Ingalls, of Chicago, writes us, referring to the above subject: "In happy contrast with the course of the *Watchman*, and many other nominally religious papers, is that of the *Christian Register*, of Boston. The *Register* has kept its pages clean. The editor told me not long since that the paper might have received fifty thousand dollars for such advertisements had it not declined to insert them."

THE ARKANSAS STATE MEDICAL SOCIETY holds its Eighth Annual Session at Little Rock, May 30th and 31st.

CHLOROFORM BREATH IN GASTRIC DISTURBANCE.—There is a symptom of gastric disturbance in children which I have never yet seen mentioned in any text-book, French or English, and yet it is almost invariably constant and generally to be met with at the *début* of the affection, so that it may be considered as a sure premonitory sign, I mean that of the breath, which smells as if the child had freely inhaled chloroform. I have always found that this "chloroform breath" not only commenced with the gastric disturbance, but continued during the whole period of the malady, and that its cessation indicated also a cessation in all the other general symptoms, fever, vomiting, etc., and consequently a return to health. I have remarked this peculiar odor in children of every age, and once in a grown-up person; it was then very strongly marked. I do not pretend to be bringing to light anything new, but I have never heard this peculiar symptom alluded to anywhere.—*Medical Press and Circular*.

THE LANCET ON BICYCLES.—A writer in the *London World* says: "I seldom read *The Lancet*, because when I do I generally discover that if I do not give up something or other I shall die before a week is over. Just now this alarmist organ is explaining to bicyclists that they are storing up for themselves many fearful maladies. Not satisfied with airing this trash, *The Lancet* goes on to express a hope that bicycles should be taxed, in order to prevent, so far as is legislatively possible, young men destroying their constitutions by riding on them. This is, indeed, protection with a vengeance. Were everything which *The Lancet* condemns taxed, we should be in a fair way of paying off the national debt in a few years. Unfortunately for *The Lancet*, bicyclists are so lost to all proper sense of science as to enjoy better health than before they took to their machines."

TREATMENT OF FURUNCLES.—It is well known to-day that the matter of furuncles is inoculable spontaneously, and it is considered that this spontaneous inoculation is encouraged by the softening of the epidermis from the employment of the poultice so often used in this affection. The primitive boil becomes thus the point of departure for secondary ones, which manifest themselves in the neighborhood. To prevent this inconvenience M. Labbé had the idea of employing successively for the dressing of furuncles a solution of chloral or phenic acid, but he perceived that this dressing, which was undoubtedly antiseptic, did not hinder the softening of the epidermis; it was thus he had recourse to collodion, a layer of which he placed around the furuncle. The result an-

swered to his expectations, for no secondary evil appeared. M. Pasteur discovered the microbe of the furuncle, which he found situated at the summit of the pustule. However, it will be borne in mind that secondary evils do not always depend on auto-inoculation, but often are the result of a diathesis at present not well understood.—*Medical Press and Circular*.

AN INTERESTING DECISION REGARDING THE PLEA OF INSANITY.—In a murder case appealed from Clarke County, the Supreme Court of Indiana has made a ruling that has attracted wide attention. The defence in the case was the insanity of the prisoner. On the trial the judge charged that the law presumes sanity in all cases, and the burden of overthrowing the presumption is upon the person who alleges insanity; but if the evidence given by defendant has been sufficient to raise a reasonable doubt of his sanity, then the general question is presented to the jury whether or not the crime was committed by him while responsible for his acts. If a reasonable doubt exists as to the defendant's sanity, he is entitled to the benefit of the doubt.

The Supreme Court says: "The proposition that the burden was upon defendant of creating by affirmative evidence as to his sanity is erroneous. The burden was upon the State to establish, beyond a reasonable doubt, every material averment in the indictment. One of these was malice. There can be no criminal intent when the mental condition of the accused is such that he is incapable of forming one, and the burden is upon the State to prove that when the offence was committed the mental condition of the defendant was capable of forming an intent. The burden is upon the State."

THE FINANCES OF THE BRITISH MEDICAL JOURNAL.—The Financial Statement of the British Medical Association for the year ending December 31, 1882, is an interesting document as showing the earnings and expenses of a great medical organization. The total expenses for the journal are somewhat over \$50,000. The various expenses of the Association ran the sum up to about \$80,000. The receipts from subscriptions and advertisements amount to above \$70,000, leaving a balance of over \$10,000 profits. The expense for the editorial work and for contributors amounts to \$13,000.

ITALIAN MEDICAL MEN IN PARLIAMENT.—Seventeen medical men have been chosen members of the Italian Parliament at the last general election. Among them are Drs. Bacelli, Panizza, Semmola, Sperino, and Tommasi-Crudeli.

UNIVERSITY OF VIENNA.—The number of students in the medical faculty of the University of Vienna during the session recently ended was 1,750, against 1,412 in the corresponding period of last year.

PASTEUR.—On the reassembling of the French Chambers, the government intend submitting a bill to raise Dr. Pasteur's yearly pension from 12,000 to 25,000 francs.

ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.—The fifty-first annual meeting of this Association will be held at Liverpool, July 31, August 1, 2 and 3, 1883. Dr. William Strange will preside. An address in surgery will be delivered by Mr. Reginald Harrison, and one in pathology by Dr. C. Creighton. The business will be conducted in ten sections.

THE FREEDMEN'S HOSPITAL AT WASHINGTON, D. C.—The First Comptroller of the Treasury, in examining the accounts of Dr. Josephs, late disbursing clerk of the Interior Department, has discovered certain irregularities in connection with the accounts of the Freedmen's Hospital. It is alleged that part of the appropriation for clothing for that institution was paid out for salaries of officers. The amount paid for salaries in excess of the appropriations for that service is not stated.

Original Lectures.

THE DETERMINATION, BY THE GENERAL PRACTITIONER, OF THE NECESSITY FOR WEARING GLASSES.¹

By D. B. ST. JOHN ROOSA, M.D., LL.D.,

PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL; PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE UNIVERSITY OF VERMONT.

LECTURE II.

GENTLEMEN—We are again to assume that we are general practitioners, with a fair knowledge of the anatomy of the eye, and that we are armed with a case of glasses, comprising lenses which run from *five* to *sixty* inches focal distance, and that we have a set of test-types. With these aids we are to determine, in a given case, whether the condition is such as may be diagnosticated by us; and, if diagnosticated, treated. I begin with a case of which I know as little as you do, never having examined it. This patient is twenty-four years of age, and he consults a doctor on account of his eyes. He says that he sees specks before his eyes, that the eyelashes are falling out, and that the inside of the lids feels rough when he is going to sleep. He can see at a distance; it does not trouble him to read; his eyelids look well. There is a slight blepharitis, a little more than hyperæmia. There is an excess of secretion from the Meibomian glands, and the hair-follicles are in an unhealthy condition. As general practitioners we have seen it stated, on fair medical authority, that people who do not wear glasses when the anatomical length of the eyeball demands them, sometimes suffer from blepharitis or conjunctival catarrh. We are therefore on the look-out to see if any of the cases of this kind that occur in our practice may not be due to a failure to wear glasses to correct hypermetropia, myopia, and astigmatism.

Having inspected the lids, cornea, iris, and conjunctiva, our next step will be to determine, by means of the test-types, what the vision is. We find that the vision of the left eye (V. L. E.) is $\frac{2}{20}$ —that is, he miscalls some letters of those that should be seen at twenty feet, but he names the most of them correctly. The vision of the right eye (V. R. E.) is $\frac{2}{20}$. We now know that this patient has slightly defective vision in his left eye, but we have not yet determined whether it is myopia or hypermetropia; nor do we know but that there may be added another condition, known as astigmatism. How shall we begin in order to find out whether it is myopia or hypermetropia? If we place convex glasses before his eyes, if he is myopic, he will reject them, because they will make his vision worse. They make the myopia worse by increasing the existing anatomical defect—that is, elongation of the diameter of the eye from before backward. For, as I said in the preceding lecture, a convex glass placed in front of the eye is but adding to the convex lens inside of the eye, and increases its refractive power.

With both eyes open, the patient makes but one mistake in reading the bottom line at twenty feet. Now we will put a convex glass before the eyes, and he says at once that he is sure his vision is made worse, but not very much so. The glass which I use is one of forty-

eight inches focal distance. I will next use a glass which is of sixty inches focal distance, and if he is myopic his vision will be made worse even with this weak glass. He does not see worse, but better. He now makes out all the letters, he says, and therefore he is not myopic. He is probably hypermetropic, and probably would get on better with a pair of convex glasses. But his case is not like that of the little girl whom we prescribed for last week, and who could see equally well with or without glasses, and equally well with glasses of considerable power.

This is a case where the patient sees normally with a very weak glass, and not quite normally without one, and it differs in degree from the one seen last week. It is a case of *manifest* hypermetropia, because he sees better by the aid of the convex glass. There may be a larger degree of hypermetropia concealed. Can we, as general practitioners, go farther? We now know that he has a certain amount of hypermetropia, but it is so small that it is not to be practically considered, if there is no more. Can we, without the ophthalmoscope, find out if there be any more? As general practitioners we must know that there is an agent, the sulphate of atropia, which, when put into the eye, will paralyze the ciliary muscle, and if there is any concealed hypermetropia, that it will exhibit it. Of course, we then come at once to another kind of hypermetropia. We have already demonstrated a manifest hypermetropia, and a hypermetropia that is called facultative, or, so to speak, voluntary. A case of manifest hypermetropia of a very slight degree we are now discussing. In it vision is only normal, *i.e.*, $\frac{20}{20}$ by the aid of convex glasses. Facultative hypermetropia was demonstrated last week. In this last-named form vision is equally good with or without convex glasses.

It may be that the sulphate of atropia will reveal a degree of hypermetropia, which is entitled to consideration, and which requires glasses of 36- or 30- or 24-inch focal distance to correct. In order to get full paralysis of the ciliary muscle we must use a solution of *four grains* to the ounce of water, for several days in succession, not less than *two* days, better still from three to five days, dropping in a drop *three* times a day, and then, if the patient sees better with, than without a convex glass, the glass with which he sees best at a distance is the glass measuring the hypermetropia, which has been concealed.

From what we have read as general practitioners, we know that we have a right to suspect a certain degree of concealed or latent hypermetropia in any case where there is a slight manifest or even a facultative hypermetropia. In other words, the total hypermetropia, or the true refraction of the eye, is not usually revealed unless the ciliary muscle be put completely at rest. Let us prescribe for our patient, however, on the basis of what we have learned to-day. If, however, the blepharitis be not relieved by the weak glass, we may then use the atropine to determine if there be such a concealed defect, and that we are justified in using a stronger one.

It would be possible to measure the refraction by using an ophthalmoscope, but this instrument is not necessarily in the hands of the general practitioner, and we ignore its use for our present purpose of diagnosis.

I will now test each eye separately with the finest type, and see whether the defective vision in the left eye may not be due to lesion in the cornea. He reads the finest print fluently, at more than six inches from the eye, and the proof is almost positive that his trouble is one of refraction, and that his other trouble, consisting of a mod-

¹ Delivered at the University Medical College, Session of 1881-82.

erate form of conjunctivitis, is secondary to the strain of the ciliary muscle. Over and over again, I have seen such cases cured, for the time, by the aid of atropia alone.

In conjunction with treatment by glasses, you may advise him to keep his eyelashes clean by the use of a solution of bi-carbonate of soda, one drachm to eight ounces of water, which will dissolve the dried mucus, and that is about all he requires except the glasses.

MYOPIA.

Our next patient is a man of twenty-six years of age, who says he cannot see at a distance; as a student he could not read letters upon the blackboard, but he can see to read fine print. It suggests itself, then, if he cannot see at a distance, cannot recognize places or faces, cannot read letters upon a blackboard at the distance from it that a student ordinarily sits, and still can read fine type, that he may have manifest hypermetropia, which would impair vision for distance, without interfering with vision of objects a few inches from him.

We may make a test at once with fine type, for we have physiological knowledge that will enable us, without glasses, without any aid except test letters, to determine as to the probabilities in his case.

The physiological fact which we call into service, is what is known relating to *accommodation of the eye*. We know that this accommodative power is exercised by the action of the ciliary muscle upon the crystalline lens. We know, from our knowledge of optics, that the rays of light coming from a near point are divergent, and the nearer the object is to the eye, the more divergent are the rays. We know that it will take a thicker lens to cause divergent rays to come to a focus upon the retina than those that are parallel; that it will require more muscular power to cause the lens to become thicker, so that the divergent rays which pass through will focus exactly on the perceptive layer. We also know, from anatomical and physiological knowledge, that a short-sighted eye is longer, from before backward, than a hypermetropic eye; and that it is also longer than the normal eye.

We see, then, that if a person starts with an eye which is too long, when he comes to read fine type, when he comes to look at objects near at hand, he has an advantage over the person who has eyes of the right length, or who has eyes that are too short. The inference is that if this man is myopic, he will be able to read fine type nearer to the eyes than if he is hypermetropic or emmetropic, because divergent rays do not trouble him. The myopic eye, or the one that is too long, is adapted to them, whereas the normal eye is adapted to parallel rays, and the hypermetropic eye is adapted to convergent rays.

Now we know from observation carefully made and corroborated and laid down in tables, that the nearest point of exact vision for fine print of an eye which is normal, at twelve years of age, is $2\frac{2}{3}$ inches, and as we increase the age the near point becomes farther off, because the power of the ciliary muscle weakens in time, and also because the lens itself becomes more rigid than in youth. At twenty-five years of age, therefore, we find that the near point is 4 inches; at forty-five years 8 inches, and at sixty years of age the near point is at 24 inches.

In contrast with this, notice the near point for the myopic eye. At the age of sixteen years it is $2\frac{2}{3}$ inches, and at the age of forty years it is the same. The near point does not change; does not recede; and this is a great advantage for reading, sewing, and the like. If this man, twenty-six years of age, has a near point, a great deal nearer than a person of the same age whom we know *not* to be near-sighted, we shall at once suspect that he is myopic.

You will always have the means for testing whether or not this be true. That is, you will test for the near point of some person of the same age, who sees perfectly at a

distance, and then compare the result with that obtained by testing the eyes of the person who is suspected to be near-sighted or myopic. The man whom I now examine, who says that he has always been able to see objects clearly at a distance, reads fine type at the distance of $4\frac{1}{2}$ inches, and you see that it corresponds pretty well with the figures given in Donders' table. He is of the same age as our patient whose near point for the same object is $3\frac{1}{2}$ inches. The probabilities, therefore, are that he is myopic. In order to assure ourselves of the absence of errors in observation, I will put a glass before the eyes which I am quite sure will not do him any good.

Before doing this let us test his vision. [Test-types used.] We find the vision in the left eye (V. L. E.) $\frac{1}{200}$; and in the right eye (V. R. E.) $\frac{1}{200}$. We have also seen him read fine type fluently, and we do not believe that he has neuro-retinitis, detachment of the retina, amaurosis, or cataract. He is probably myopic; and I conclude he is considerably so because his lack of vision is so great and his near point is so near. I will now put on a *weak convex* glass. He says that his vision is made a little more indistinct. I will next put on a concave glass of thirty inches focal distance, which practically shortens the eyeball considerably. With this glass he can make out "A," the first letter of the test-types. We have raised his vision to $\frac{2}{200}$. Now I will make a long leap in choice and use a glass of sixteen inches focal distance. His vision is now raised to $\frac{3}{200}$. I next use a concave glass of eleven inches focal distance, and his vision is raised from $\frac{3}{200}$ to $\frac{4}{200}$. Shall we stop there? Oh, no.

We have skipped over two or three numbers in our trials. In myopia we give the *weakest* glasses that will fully correct the error. *In hypermetropia we give the strongest glasses which will fully correct the error. The danger is in giving too weak glasses in hypermetropia, and too strong glasses in myopia.* Why? Because there is in some eyes, under strain in constant work, a kind of accommodative myopia; that is, the ciliary muscle is not at rest in a myopic eye any more than in a hypermetropic eye, and there may be an excessive action or spasm of that muscle, which increases the myopia by unduly thickening the lens, and if you are not careful you may give too strong glasses. It is better to give a myopic patient a glass under than over the exact degree. The glass which will do our patient the most good is probably number 12, a little weaker than 11, which raised his vision to normal or $\frac{4}{200}$.

In young persons especially, accommodative myopia is very common. It is not safe to prescribe concave glasses for them, without first paralyzing the ciliary muscle by the use of atropia.

This, then, is a case of myopia, and we have made our diagnosis without the aid of the ophthalmoscope. Upon the basis of this examination, I will now go on and say to you what the general practitioner should know concerning myopia.

Myopia may be a congenital condition or it may be acquired. Its anatomical basis consists of an elongation of the antero-posterior diameter of the eyeball. The great problem of heredity occurs in the discussion of myopia. If the father and mother, one or both, are myopic, will the children be myopic? Some of them will; probably not all of them. In some of them there will be a return to the normal type, a tendency which, according to Darwin, will always preserve the human race from degeneration to any great extent. I speak of this fact because of those who are fearful that the human race is gradually undergoing degeneration, and finally will succumb to the assaults of civilization, and that at last we shall all be myopic, that our grandchildren will uniformly have detachment of the retina and other consequences which flow from myopia. No; the laws of heredity, whatever they are, may be overcome—may be shorn of some of their power by circumstances. The child born with eyeballs too long may be encouraged in early

life to look only at large objects, to play with good-sized toys, to always live in a well-lighted room, discouraged from reading by twilight, encouraged to shoot, and to play games which involve looking at a distance, and so forth. In other words, circumstances may control his hereditary tendency to a certain degree, and may finally overcome in the race, to a large extent, the myopic tendency which may have been transmitted to us. The myopic tendency which has come upon the German people, until it is nearly a scourge, might be modified if the Germans could be induced to banish their abominable type, cease the everlasting writing upon most trivial subjects in offices and bureaus everywhere, and place themselves under conditions favorable to overcoming the tendency. In other words, if they would imitate their Anglo-Saxon neighbors across the channel, do a little more hunting and driving and riding, and work less in enclosed gymnasias and exercise halls.

But there is an acquired myopia. Children are born into the world with eyeballs too short, and by a reversal of the proper conditions of life their eyeballs may become too long. Suppose that I wish to produce elongation of the eyeball, how can it be done? I would do this: I would allow the child to play with only the smallest toys, train him in picking up pins, in looking out finely printed names on a map, and I would be careful to get the most illegibly and finely printed books for him to read; set him at work in the evening by the aid of a tallow dip, or by the light of a wood-fire; in the daytime have him sit as far away from the light as possible; see that the light used for reading or work is shaded by the arm; see that all outdoor occupation is neglected; discourage his playing at ball with other boys; see that he is fed with farinaceous food only; that he is washed once in four weeks, if at all; has insufficient clothing in the winter and is overclad in the summer. In other words, make his condition as hard as possible; place him in a position so that when he looks upon a book he will have to strain his utmost to get an image upon the retina; and in a large number of cases I think you will produce myopia. How would it be done? This straining to see in a poorly developed child would fill the blood-vessels in the ciliary region, would prevent the return of venous blood, and there would be congestion. The next step would be the stage of softening, and then the coats of the eyeball would yield, and elongation sufficient for our purpose will have been accomplished. A one hundred and twentieth of an inch is a great deal in an eyeball.

This is myopia; this is elongation of the eyeball, either congenital or acquired. The old notion was that myopia depended upon change in the curvature of the cornea. That is a kind of acquired myopia which occurs in certain diseases, occurs with conical cornea, so called, and after an inflammatory affection of the cornea; but it is not the myopia which we are considering. It is not the myopia to be remedied by glasses, to be diagnosticated and prescribed for by the general practitioner. The latter, the true myopia, depends upon elongation of the entire eyeball from before backward.

As general practitioners, you will be called upon to see to the building of school-houses, to the admission of light, and to the nutrition of the children. Prevention of disease is to be the function of the medical man of the future. The curing of disease will always remain his dire alternative where it cannot be prevented. Your greatest efforts should be directed toward the prevention of disease. The ignorance of the community, and the insuperable insolence with which some of our officials receive sanitary plans made for them, the political corruption of every age and time, are obstacles which will prevent you from carrying out your purposes, even if you were sufficiently skilled to obviate every disease. Thus there will always be, besides accidents, plenty for you to do in the way of treatment. Nevertheless, I say again, your great work as practitioners in the future will be in the prevention of disease. In the prevention of myopia

there is a great field before us. It would be very sad for this country if we came into the condition in which Germany exists with reference to myopia, even if there go with it the culture and scientific acquirements which have made Germany so easily first in many of the great movements in the scientific world. To become a myopic nation, even with such a reward, would be paying too great a price. A myopic eye is a diseased eye, the hypermetropic eye is an undeveloped eye. The emmetropic eye is the normal eye, but it very seldom exists. But the dangers from the myopic eye are much greater than those from hypermetropia. The chief danger to a myopic eye is that changes in the light-perceiving portion, the image-forming portion of the eye, the retina, may render it unable, even with the greatest muscular exertion and under the most favorable conditions, to form an accurate image. These changes will be due to the increasing softening and elongation of the eyeball, and the constantly acting congestion which precedes it. The elongated eyeball is also in danger, from sudden exertion, of being fatally injured, as to sight, by detachment of a portion of the retina. We are, therefore, very anxious as sanitarians to diminish the amount of myopia.

Long ago Mr. Ware, who wrote on myopia first of all of those who have said so much on the subject, discovered that it was very rare in the English Foot Guards, and experience shows that it is very rare in England as compared with Germany, for reasons already mentioned. I predict that it will never become a scourge in this country, because of the tendency among our people to use the rod and gun, to ride upon horseback, and to work up our boundless facilities in the way of open-air exercise. Thus I return to the statement, that you as sanitarians must attempt to prevent myopia by advice to your patients.

Our patient here has a sound retina, for he has perfect vision with glasses. Just now, it is a little troublesome for him to wear glasses perhaps, but upon the whole it is an advantage. He will have the advantage of those who are emmetropic when time has made his hair gray, weakened his ciliary muscle, and made his lens a little harder; for then his long eyeball will stand in good stead for him, and he will read the newspaper with ease without glasses. And this is all the advantage there is in myopia. In myopia glasses are not needed for reading in old age. As to the popular notion that it decreases, it is utterly incorrect. An eyeball once elongated remains of the same length. A spasmodic myopia may exist, and that may diminish, but not a myopia that depends upon the pathological changes I have mentioned.

PERNICIOUS JAUNDICE.—The following case is related by Dr. Verdalle in the *Journal de Médecine de Bordeaux* of April 1, 1883. A young man, nineteen years of age, of temperate habits and of good physique, was admitted to hospital complaining of nothing but excessive lassitude. He had marked jaundice with clay-colored stools, but there were no nervous symptoms and no fever. The liver was normal in size and not tender on pressure. Laxatives and Vichy water were prescribed, and no further attention was paid to the case, it being supposed to be one of simple catarrhal jaundice. Five days later there was vomiting, which was controlled by simple remedies. Four days after this, suddenly, during the night, the patient became wildly delirious, in which condition he remained until the morning, when coma set in. There was absolute unconsciousness, reflex movements were abolished, the pupils were dilated, the pulse was sixty and regular, and the temperature was sub-normal. Death ensued the following night. The autopsy revealed acute interstitial hepatitis. The liver was of normal size, and showed upon its surface and within its substance a number of irregularly shaped spots of a bright yellow color. There were numerous small ecchymoses upon the gastric mucous membrane. The brain and meninges presented no traces of inflammation.

SUCCESSFUL LUMBAR COLOTOMY IN AN INFANT OF TWO MONTHS.

By GEORGE R. FOWLER, M.D.,

SURGEON TO ST. MARY'S HOSPITAL; SENIOR SURGEON TO BUSHWICK AND EAST BROOKLYN DISPENSARY.

ANNIE S—, two months old, was brought to my office on December 6, 1881, with the following history: The mother, who has borne four well-formed and healthy children, states that while pregnant with this child, and when about five months advanced, she cared for another child suffering from an ischio-rectal abscess, which was opened by my assistant, Dr. Beasley, near the margin of the anus. The patient, an otherwise well-developed child, at birth exhibited no subjective symptoms of any malformation; although the parents now recall that but very small and purely liquid feces were discharged up to within two weeks, when these ceased. It was noticed that urine was voided, up to this time, when no fecal matter was found upon the napkin, and likewise that a stain of feces occurred when no urine was voided. Examination reveals a distended abdomen, tympanitic except over the transverse and descending colon. The navel is protruding, and the superficial abdominal veins are enlarged and prominent. There is no anus. No trace of a recto-vaginal fistula can be discovered, although such must have existed.

On December 7th, the child under chloroform, assisted by Drs. Beasley and King, I attempted to find the opening between the vagina and gut, through which the fecal matter had escaped. Failing in this, I divided the tissues posterior to the vagina in the median line directly back to the point of the coccyx. The dissection was then carried carefully upward until the peritoneal cavity was reached, above the cul-de-sac of Douglas. At a point about midway between the ostium vaginae and the upper limit of the vagina posteriorly a membranous septum was found, dividing the canal into an anterior and posterior cavity; it was thought that this latter was the one leading to the rectum, but patient search failed to reveal any opening. In this emergency I performed colotomy through the left loin as follows: The child was placed upon its right side, and the outer border of the quadratus lumborum muscle made out as far as practicable; this latter was found to be attended by some difficulty, on account of the extreme youth of the subject. The oblique incision, recommended by Bryant, was then made, about one and one-half inch long, beginning at the supposed site of the outer border of the quadratus lumborum muscle and extending obliquely downward and forward. The skin and superficial fascia, a portion of the latissimus dorsi, the external oblique, internal oblique, and transversalis muscles were divided in turn, and the transversalis fascia exposed. Upon incising the latter, the lower border of the kidney was brought into view, lying at the bottom of the wound. It was found necessary to divide the peritoneum before the colon could be reached; this being done the latter rose prominently into sight, and was easily identified. Having taken the precaution to pass a ligature through the walls of the colon and given the same in charge of an assistant, I incised it for a distance of about three-fourths of an inch in a direction parallel to its long axis; a sponge wrung out of warm carbolized water was held over the anterior angle of the wound to prevent fecal matter from passing into the cavity of the peritoneum. Upon opening the intestine there escaped a quantity of feces and gas. The edges of the opening into the gut were now stitched by interrupted sutures of silk to the incision in the integument, care being taken to frequently wash away the fecal material which from time to time oozed from the opening during this stage of the operation. Owing to the traction made upon the colon, the anterior angle of the incision into the perito-

neum slipped inside the abdominal cavity, and could not be secured; the posterior angle was included in the sutures uniting the intestine to the skin. Several times during the operation the little patient stopped breathing, and frequent efforts at resuscitation were necessary; these consisted of artificial respiration by Sylvester's method, slapping the precordial region, inhalation of nitrate of amyl, inverting the patient, and upon one occasion the hypodermic injection of gin, the only available stimulant; this latter was found to be rapidly efficacious, probably owing to the pain produced by its irritating qualities.

A large cup-shaped sponge, wrung out of carbolized water and held in place by a napkin, was the only dressing employed for the wound in the loin; the perineal wound was dressed with carbolized oakum after thorough cleansing with 1 to 40 carbolic solution. The little patient was placed in its mother's arms, where it soon rallied from the chloroform and after an hour slept comfortably. The sponge was directed to be changed frequently, as there issued almost continually from the artificial anus large dejections of a natural yellow color. The carbolized oakum dressing over the perineal wound was ordered to be changed, and the parts bathed with 1 to 40 carbolic solution, whenever soiled by the urine. The following is the record of the further progress of the case:

December 7th, evening.—Pulse, 140; temperature, 100° Fahr.; child crying lustily and is quieted by nursing. Ordered two drops of deodorized tincture of opium to be given every hour when in pain.

December 8th.—Pulse, 160; temperature, 102½° Fahr. Patient is moderately under the influence of the opiate. Size of abdomen much diminished; large quantities of fecal matter of the consistence of putty is coming away with gas. Perineal wound glued together by plastic exudation.

December 9th.—Pulse, 120; temperature, 98½° Fahr. Has rested quietly with but a single drop of the deodorized tincture of opium during the last twenty-four hours. Bowels moved through artificial anus four times during the same period. Suckles well; mother thinks that a slight fecal stain occurred upon the dressing over perineal wound.

December 10th.—Pulse, 120; temperature, 98½° Fahr. Child rested well during the night; looks bright and natural this morning. Bowels have moved three times during last twenty-four hours and has taken but one drop of the deodorized tincture of opium during that time. Tissues around opening slightly reddened. Good union of the edges of the incision in the colon to the integument.

December 11th.—Pulse, 120; temperature, 98½° Fahr. Patient's condition, so far as can be determined, exclusive of the opening in the loin, is perfectly normal. Ordered carbolized cerate for the edges of the opening in the loin. The mother showed me a stain upon the lower napkin which is undoubtedly that of fecal matter; thus far, however, the napkin has been also wet with urine.

December 12th.—Pulse, 125; temperature, 98½° Fahr. Slightly uneasy; removed sutures; wound healthy. Bowels move through artificial anus four or five times in twenty-four hours. Lower wound united perfectly. Discharged cured so far as operation is concerned.

I subsequently attempted to find the termination of the rectum by passing flexible bougies through the artificial anus; these were arrested at about the site of the sigmoid flexure. Further operative procedures were deemed inadvisable. The child is strong and healthy, and seems to suffer no inconvenience from the artificial anus.

Remarks.—This is one of those rare cases in which there seems to have been a fecal fistula terminating into the vagina, conjoined with absence of both rectum and anus. Cases in which a fistula opens into the vagina

exits are commonly those in which the rectum is present, and may be regarded as the cases most favorable for operation, excepting, perhaps, those cases of the malformation in which there is simply absence of the anal opening, and in which the bulging gut can be plainly felt and seen through the integument or occluding membrane. From the fact that fecal matter had come away early in the patient's history, when no urine stained the napkin, and that, per contra, urine had been voided when no fecal stain accompanied it, it was reasonable to suppose that I had to deal with one of those cases in which the rectum was present, the fecal fistula opening into the vagina, the anus only being absent. Such being the case it would have been comparatively easy, upon locating the opening into the vagina, to have passed a curved director into the rectum through the opening, directing its point downward and backward, and upon this as a guide, made the necessary opening for the purpose of establishing an anus in the normal situation. The fact that the urine and feces were voided separately was an almost positive indication that the case was not to be classed among those in which the fecal fistula opened into the bladder or urethra. It was, therefore, with the greatest confidence that I expected to be able to relieve the patient by the simple operation above indicated. The event proved, however, that I had to deal with one of the most difficult, as well as rarer forms of the deformity, and the question as to what was best to do in such an emergency at once arose. Exploratory operations, such as I performed, *i.e.*, that of incising the tissues in the median line and following the curve of the coccyx, and dissecting carefully upward in the hope of finding the cul-de-sac in which the gut sometimes ends, as frequently fails as it succeeds; unfortunately it is not devoid of danger as well, for diffuse inflammation of the sub-peritoneal cellular tissue and peritoneum generally bring about a fatal issue. Again, in such an operation, there is no certainty that the rectum, even if it exist at all, lies in the median line, and a dissection may be carried up alongside of the gut, so as to open into the peritoneal cavity, or a trocar may be plunged into what appears to be the bulging cul-de-sac at the bottom of the wound, and only a protruding fold of peritoneum be perforated. Thus it may occur that the intestine is near at hand, and yet be missed entirely.

Although in this case an attempt was made to find the rectum by dissecting up the perineum, yet I believe that such a course should not generally be followed. The uncertainty of finding the gut, the possibility of a fatal issue resulting from traumatism inflicted upon the peritoneum and its underlying connective tissue, and the liability to hemorrhage from some of the branches of the internal iliac artery, all combine to render the procedure an exceedingly hazardous one. Taking everything into consideration, therefore, I think that the advice of Holmes should be followed, and in cases in which no guide to the actual presence and location of the gut exists, as, for instance, a fecal fistula through which a probe can be passed into the rectum, the operation of colotomy should be at once performed. This operation is not more dangerous than the exploratory one through the perineum, and possesses the advantage of relieving the patient's immediate wants; it is also comparatively easy of performance.

What I consider of the greatest importance, however, is the immediate performance of colotomy in the class of cases under consideration, and a point that suggested itself to me at the time when I attempted, in this patient, to pass a flexible bougie through the artificial anus in the hope of locating a rectal pouch, is the feasibility of making available the opening in the colon for purposes of diagnosis. A sound or guide may be passed through the latter downward and backward, thus demonstrating indubitably the presence or absence of a rectum; in the former case the sound will form an infallible guide upon which to direct the incision for the establishment

of an anus in the normal location. Should such prove successful, the opening in the colon can be closed at once, or at a subsequent operation. On the other hand, should it be discovered that no rectum exists, the patient will have been saved from the dangers attending the uncertain exploratory operation, and the operation of colotomy, to which it must finally submit, be already accomplished.

That the child in this case had attained the age of two months before serious symptoms of intestinal obstruction occurred is worthy of note. The explanation most reasonable is that, in the earlier part of its existence, the feces, being almost purely liquid, readily found their way through the fistula; even then, according to the mother's statement, the discharges were only sufficient to merely stain the napkin in small spots. Later on, as the fecal matter became more solid, it could not find its way through the opening, and gradually accumulated; in consequence of this the track of the fecal fistula gradually contracted until it became so small as to be undiscoverable. That the fistula, in some instances, may be sufficient during early existence, and yet not fulfil the requirements of later life, is shown in a case of Mr. Lane's, at St. Mary's Hospital, London, in which the patient lived to the age of four and a half years.¹ By this time the intestine, from the insufficiency of its outlet, had formed an immense pouch which filled the whole pelvic, and encroached considerably upon the abdominal cavity. Ricord relates two cases in which the opening into the vagina was sufficiently large to answer all the purposes of an anus; the subjects, both females, reached adult life and apparently suffered but little inconvenience from the malformation. In these cases the fistula and its opening must have been large, and a sphincter muscle developed around the latter.

In the matter of the influence of maternal impressions upon the arrest of development in this case I have very little to offer, except to express my disbelief in such influences. The period at which this influence was supposed by the mother to have been instrumental in affecting her offspring was too late in intra uterine gestation to have preceded the time when the anus and rectum, separately developed, meet and coalesce to form the complete intestinal canal.

THE TEMPERATURE OF SCARLATINA.—Drs. Kuvshinsky and Pastor have undertaken a large series of observations on the course of the temperature in scarlet fever, and have concluded therefrom as follows:

1. In a vast majority of the cases, the temperature, after a lysis on the sixth to the tenth day, remained normal during the next three to eighteen days (mostly fourteen days), and then again rose to febrile figures (in some cases to 104° F. and above). Within one to five days it again gradually returned to the normal. In some few cases there were observed similar tertiary elevations of temperature, generally on the thirty-fourth to the thirty-sixth day of the disease.
2. Simultaneously with these secondary elevations of temperature, there were almost invariably found some other characteristic morbid phenomena, as swelling of the lymphatic glands (mostly cervical), more or less pronounced renal affection, reappearance of a diffused angina, inflammation of the endocardium, extreme weakness of pulse, and, lastly, in four cases, reappearance of the scarlatinal rash with subsequent desquamation. Considering the facts stated, Drs. Kuvshinsky and Pastor arrive at the conclusion that re-elevations of temperature in the course of scarlet fever, being far from accidental, are caused by the scarlatinal infection itself. The latter, therefore, in common with some other infectious diseases, shows a disposition to run its course with greater or lesser oscillations in the development of various symptoms of the pathological process.

ON THE
IMPORTANCE OF RECOGNIZING THE CON-
DITIONS KNOWN AS STHENIC AND AS-
THENIC, IN DIFFERENTIATING THE CAU-
CASIAN AND AFRICAN RACES; AND IN
DISEASES GENERALLY.

By HARVEY L. BYRD, M.D.,

PRESIDENT AND PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN THE BALTIMORE MEDICAL COLLEGE, BALTIMORE, MD.

THERE are two good old words with explicit significance, which were much and properly used for the most part by our grandfathers in the profession, that seem to have lost their value in a great measure in the estimation of some of our modern teachers and writers upon medical subjects, which might be profitably restored to their former prominence and importance in our professional literature of the present day. Should this brief communication, therefore, produce no other beneficial result than that of recalling attention to their significance and their peculiar fitness to occupy an enduring place in our nomenclature, and thus to keep the two widely separated and almost diametrically opposite states or conditions of the human organism in health and in disease, always prominently and perspicuously before the medical mind, a most important step will have been taken toward wiping away some of the flimsy drapery with which certain morbid conditions have been sought to be clothed by a few modern writers, and many of the hair-breadth distinctions between diseases, attempted to be made by others, bridged over or annihilated altogether. The import of the good old Greek, *sthenos* and *asthenos*, stands out in bold relief before the mind of the medical philosopher, of much practical experience in the profession, whenever he is called to the bedside of disease. And like the Pillars of Hercules, they must ever mark the entrance into the great sea of successful professional practice, where their significance is obeyed as it should be. It is not, therefore, claiming too much for those words to add, that a correct knowledge of the conditions which they represent, establishes the only true basis, or foundation, upon which an accurate diagnosis can be formed, and consequently a correct therapeutics instituted in the treatment of diseases. The value and importance, then, for the revival and a more general use of those terms in our discussions and treatment of the thousand ills to which flesh is heir, must be obvious to the intelligent mind upon a moment's consideration; particularly as they may be readily observed as intimately associated with the action of morbid agents in the development of disease, and sometimes, if not frequently, important factors as predisposing, and, possibly, even the exciting causes of certain diseases in either race, and among many conditions of mankind. But there is absolute necessity for the use of these words, if we would appreciate at their proper value certain *normal* or natural states and conditions as we find them existing in the *primordial* types of the genus homo. And long experience has satisfied my mind completely that professional success of a high order is unattainable where the Caucasian and African races are contemporaneously attended either in hospital or private practice, without heeding the natural tendency of disease to a sthenic state in the white and an asthenic condition in the negro race. This state of things is conspicuously marked in endemic and epidemic visitations, when the two races are under the action of the same morbid agent or influence for a certain space of time. The natural and radically distinct differences and peculiarities, anatomical and physiological, which exist between the negro and the white man, have been already sufficiently referred to in a previous article in this journal, when speaking of the primordial races of man; and hence it will only be necessary to say a few words, a little further on in this paper, on the effect of *materies morbi*, and the action of therapeutic agents

upon the respective races to render the entire matter clearly intelligible to the reader.

As both the white man and negro are exotic, and have resided contemporaneously in this country for a sufficiently long period of time under the same and similar climatic, hygienic, and physical surroundings to be equally well known, they are, therefore, in a suitable condition to be studied in regard to their predisposition to, and their ability to withstand, the influences of morbid agents, when acting as chief factors in the development of endemic and epidemical diseases. Whilst presenting some leading facts in support of the foregoing premises, I shall take occasion to introduce the action of therapeutic agents, as being fully in harmony with the laws which establish and control diversity in the races to which they apply; and thus develop the utility, not to say imperative necessity, for carefully regarding the sthenic and asthenic conditions as factors of the highest value in the diseases to which the races are liable. And, therefore, the absolute demand for a modification of treatment in the Caucasian and African races when suffering from the same disease. To what has been said already of the *status* of the two races must now be added the distinctions of age and sex, in order that the parallelism may be rendered as complete as possible, and thus the differentiations be perspicuously brought forth and made of practical advantage to the profession in a clearer presentation of the value of symptoms and signs at the bedside. As already intimated, the white and black races are not equally hable to impressions from morbid agents and influences.

Thus, to *Cholera*.—For twenty or more years preceding the late civil war, cholera occurred from time to time, endemically, among the negroes on the rice plantations of South Carolina and Georgia, assuming even epidemic proportions as it extended to adjacent or contiguous plantations; and though the overseers and their subordinates, and sometimes the owners or proprietors of the estates and their families even, remained upon the plantations continuously during such visitations, they enjoyed almost complete immunity from the disease. The negroes all the while manifesting the chain of phenomena so characteristic of Asiatic cholera in a malignant form.

Second.—Yellow Fever.—As that disease prevailed epidemically in the cities of the South, in ante-bellum times, the white, or Caucasian race, was the material upon which it seemed pleased to feed; and the fairer the type, all other things being equal, the greater the fatality of the disease; while the African, or negro race, was nearly exempt from its ravages. In my own experience, in the treatment of hundreds of yellow fever patients, I never saw a case of black vomit in a negro.

Third.—Malaria.—Whilst he was liable to be attacked with remittent and intermittent fever, the negro was very far less exposed to the effects of malaria than the white man, under the same circumstances.

Fourth.—Inflammatory Diseases.—The negro suffered much less frequently from inflammation of the serous and fibrous tissues than the white race, and much less also from troubles of that kind in the mucous surfaces; and though attacked with pneumonia to a considerable extent, when it appeared to prevail epidemically in the South, he did not suffer in the same ratio with the white man, though far more exposed to inclement weather and atmospheric vicissitudes. The parallelism and differentiations of the diseases to which the two races are exposed might be extended almost indefinitely; but it is thought that a sufficient number of facts have been adduced to satisfy the wishes of any who might be pursuing this branch of professional inquiry, and I will therefore hasten on, as fast as practicable, to the other salient points adverted to in the earlier portion of this paper. Any, and as far as I know, every disease that affects the white and negro races, in common, assumes a *lower grade of action* much sooner, under the same circumstances,

in the latter than in the former race, when that state is not conspicuously obvious *ab initio*. Again, I feel quite sure that I can state, with great accuracy and propriety of language, that the converse of the foregoing observations is true of diseases generally in the white race—certainly so when contrasted with morbid conditions as found in the former race. Hence, it would seem to be logically certain, that while a disease might exhibit a higher or lower grade of action, in either the Caucasian or the African, under certain circumstances, and at different times, the law depending upon difference in race is, that the type of disease in the white race is sthenic, and it is asthenic in the negro, under the same, or as nearly as possible the same, circumstances. These types will of course suffer modification or exaltation, and become more or less sthenic or asthenic, under different or varying influences; all of which are, however, too well known or easily recognized by the profession generally to require that more should be said in that connection. But these facts do not lessen the value of the preceding statements in any way, regarding the tendency of *all* diseases to assume a sthenic or an asthenic type, whether they occur in the white or negro races.

The constancy of the action of this law was strikingly exemplified in my experience in the South during the civil war, both in regard to the symptoms of disease and the treatment necessary for the two races, under as nearly the same circumstances as it is possible for them to appear. A proper appreciation of the foregoing facts is necessary in order that therapeutic applications may be judiciously and properly made in the treatment of diseases. In fact, it may be safely said that this most important consummation cannot be certainly reached in any other way. To illustrate its value, I will state a few facts that have been repeatedly observed in my professional experience. Thus, sedatives and depressants and antiphlogistics generally, whilst often called for in the treatment of acute and recent cases of disease, and manifest such prompt and decisive benefit when applied in the Caucasian, as a rule produce no good results in the negro, unless they should be used with great caution, and then suspended promptly upon the slightest evidence of depression taking place; and it may be safely said that such remedies are often productive of positive harm in his case. This fact is particularly and strikingly exemplified in the effects of bloodletting and in the action of *veratrum viride*—two of the most potent sedatives and at the same time valuable agents where their action is called for in the white race, are almost always attended with harm in the negro, and especially so when carried to the extent found useful and necessary in the Caucasian. Thus, no agents act more satisfactorily or philosophically in the subduction of acute inflammatory symptoms in the white race, or are more urgently called for in the scientific treatment of such cases, than bloodletting and arterial sedatives; and yet, if they are resorted to for a similar purpose in the negro, the greatest caution and circumspection are imperatively demanded in order that harm shall not result from their use. In the rare cases in the negro which seem to warrant active antiphlogistic treatment, tonics and stimulants are required at an early period in their management. Opium and its preparations are badly borne by the African, as a rule, and the same is true, in an equal degree, of the entire narcotic class of remedial agents in their action upon his organism.

This is an exceedingly interesting branch of professional inquiry, and though the field is so inviting as to tempt me to detain the reader much further in the presentation of many other valuable facts gleaned in it during more than two decades of active practice upon and near the rice plantations of South Carolina and Georgia, where, I may add, that in ante-bellum days the material and the opportunities for turning it to practical and valuable account were of the most abundant character, yet it seems necessary that, after a few more words or

statements of closely allied facts, this hastily written article should be brought to a close.

The hybrid—mulatto—is a factor of considerable importance to physicians who encounter him in practice to much extent. But when he is considered as partaking of the structure and *nature* of his progenitors in a nearly equal degree, it will be readily perceived that he occupies a place intermediate, or between the Caucasian and African races, in other respects also. His immunity and his susceptibility to the diseases of his progenitors, and his impressability to the action of therapeutic agents, is also of an intermediate grade between that of the races from which he sprang.

127 N. ARLINGTON AVENUE.

INEBRIETY FROM OBSCURE PHYSICAL CAUSES.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

IN THE MEDICAL RECORD of last October, I gave the notes of a number of cases of inebriety, in which the causes were unknown, even to the physicians familiar with the cases. This paper attracted much attention, and I have received a large number of letters from physicians and others relating to it. Many of these letters were histories of similar cases, or the personal narratives of the experience of the writers, who were victims, or of patients or relatives; and all are eloquent in appeal for help and advice what to do. I propose to present some of these cases, as an argument for a medical and scientific study of inebriety, above the levels of the theories of reformers and clergymen. These notes are mere outlines of cases that are familiar to every physician, and cover an almost unknown realm of pathology, psychology, and therapeutics.

The following cases are evidently the histories of the writers, and are found to be truthful from other evidence than the authors':

A. B—, born of healthy parents, and brought up on a farm. After several years of school teaching, alternated with studies at an academy, and working on the farm, he studied medicine and graduated with honors, receiving a prize. Soon after he married and settled in the country. At this time he was healthy, vigorous, and temperate from principle. Ten years after he had become a prominent, prosperous physician. He fell through the ice of a river one cold winter night, and was with difficulty saved from death. A severe attack of pneumonia followed, with a long convalescence. From this time he suffered from violent beating of the heart, with every excitement and overexertion. He began to use spirits for this nervousness, and found relief. A year later he was intoxicated and obliged to use spirits regularly to prevent this nervous state. After this (in his opinion) a series of troubles began, which came directly from his enemies, and culminated in poverty and disgrace. His wife died, and he was a chronic inebriate, and after a few years of great irregularities, was sent six months to prison. He served out his time, and has resumed practice, greatly improved in health, and is now temperate. He writes that his inebriety began from some physical condition, and that through the treachery of friends he was made worse.

From other sources I ascertained that soon after the attack of pneumonia, he drank to great excess at intervals, associated with low people, and gambled. A total change of character and impulse followed. Before he was honest, frank, and generous; now he was treacherous, secretive, and thoroughly unprincipled in conduct. He forged notes, became a tramp, and after six months' imprisonment seems to have recovered, and began to live a temperate life.

In all probability, the pneumonia was followed by heart-strain, or acute asystolism, for which spirits was a

sedative. Inebriety followed most naturally. The train of events which culminated in inebriety was physical; the nature and character of this change, and the moral paralysis which seem to follow, were largely unknown. The partial recovery following a period of forced abstinence in prison is very significant of what might have been accomplished by an early recognition and treatment of his case.

C. O. — writes me that his father died of consumption before his birth, and no other heredity is present in the family. He was always hale and strong, graduating from Yale College with some prominence as an athlete. After a long medical training he was made demonstrator of a medical college, and six years later became a full professor. He was temperate in all things except smoking. One day he became accidentally intoxicated in his lecture room, and soon after was forced to resign. He began life in a frontier city, became reckless, lost all ambition, and drank to great excess. He was finally taken to an insane asylum, where, after two years' treatment, he was given a position on the staff, and for many years has been constantly gaining in strength and vigor. From his statements, confirmed by a physician who was intimate with him, it appears that two years before he was seen intoxicated in public he drank brandy at night for its sedative effect. He was engaged writing a book, and after the active duties of the day were over he would spend most of the night in his library. He would become so nervous and restless that he could not sleep. Various remedies were tried, but at last brandy and ether was found most effectual. He failed in all his efforts to give up the use of this drug at night, until at last he appeared publicly intoxicated. He writes that inebriety began from neurasthenia and heart exhaustion, following excess of tobacco, and general neglect of healthy living.

This is no doubt correct. He inherited a defective organism and was an impulsive, nervous man, very strongly impressed by the surroundings. Had his malady been recognized in the early stages, and the treatment been prompt and effectual, a life of great usefulness might have been preserved.

An eminent physician writes of his son, who is free from any inherited defect, but who uses spirits to great excess every two or three months, spending the intervals in great exertions to prevent the further use. He was educated as a clergyman. After graduating at the seminary he was called to supply a church at a famous watering place, and was very ambitious to make a good impression and secure a call to a city church. He succeeded, but before he was ordained drank to intoxication in public. From this time he has lost all ambition and interest in the future. For a few weeks after the paroxysm of intoxication he is very active in his desire to get well and help others. His father is convinced that his inebriety is from purely physical causes. He traces it to general neglect of exercise, overwork, and failure to sleep. He thinks that he began to use spirits in the seminary for a tonic, and used it quite freely while supplying the pulpit, but always at night.

A physician reports this case: A gentleman of wealth, education, and high standing in the community, will frequently drink to excess and associate with the lowest company, in the vilest places, and in a most public way. This will last for ten days, after which he will recover and live a most exemplary life for an indefinite time. He is married, has a family, and attends church regularly. No history of heredity can be traced, but a few years ago he was defeated for Congress, much to his disappointment. He suffered soon after from an attack of asthma and fever, with a long, slow convalescence. He used spirits freely during his illness as a medicine. After recovery he was greatly irritated in the settlement of some business, and drank to excess for the first time. He was temperate up to this point, and after the paroxysm of drink will regret keenly his conduct, and make efforts to

regain his lost energy and reputation. The physician writes: "Although I cannot clearly make my belief apparent to others, yet I am convinced that he is suffering from some pathological change and disease, which began, or burst out, after his disappointment, and the fever which followed from it. I am also sure that he is more or less powerless to help himself, and needs positive medication and active treatment."

In another case reported to me by a physician: A strong, healthy farmer began to drink after recovery from a severe wound of the foot, in which he had lost much blood, and was laid up for three months. His wife died at this time, and he became gradually a notorious inebriate, spending all his property, and living an abandoned life. The exhaustion, and probably the shock, from the hemorrhage and death of his wife, acting by reflex action, broke up the normal integrity of some nerve-centres, and inebriety was only an expression of this state.

A New York physician writes: "I have a patient who never drinks except after sexual intercourse. If this is prolonged he becomes very stupid from drink, and cannot recover until he is taken to some hotel or hospital and carefully treated for two or three weeks. He has very little sexual desire, and after its gratification suffers from great depression, and a nameless agony of both body and mind, which only spirits can remove."

The wife of a physician writes of her husband, who is a confirmed inebriate, that his drinking dates from the time of her illness and injury from an accident; that for two weeks he was greatly excited, supposing she would not get well, and blaming himself for the accident. Working all day and sitting up every night, neglecting to eat or sleep regularly, and using spirits to keep up. From this time he has used spirits, and although he declares that he will and can abstain, never succeeds, or attempts it.

A noted medical teacher describes the case of his brother, which in substance is as follows: Insanity existed in the grandparents, and moderate drinking in the parents. This case was a gentleman of superior education, of correct, temperate habits, and an ambitious, proud man; but naturally very nervous and impulsive. He excelled as an orator and lecturer, and for several years occupied a prominent place on the lecture platform. Then suddenly he gave up this work and began to study law. At this time he had a severe attack of scarlatina, was disappointed in marriage, and lost most of his property in stock speculation. After admission at the bar, he began to practise in the police court among the lowest cases. A change of ambition and character was noticed. He drank regularly, and lost pride in appearance, associated with low people, became a politician, and served in the city boards. His character for honesty changed, and he became low and unscrupulous in his recognition of right and wrong. His drinking increased, and finally he was sent to prison. The doctor writes: "I am convinced that the inebriety, with change of character, ambition, and habits, all following a succession of physical and mental troubles, came from disease. He was thirty-four years old when this decline began, and the inherited predisposition undoubtedly formed the favoring soil which encouraged the growth of inebriety, and general failure of all normal brain-action."

These cases might be multiplied to fill a volume, both from my own observation and from correspondence. I am satisfied they are very common, but from want of study are passed by as poor victims of a vice which may be controlled at will. Now and then a physician, who becomes familiar with all the details of the history of a case, will recognize the presence of disease; but as this is not sustained by the prevailing opinions of the profession and general public, he has no incentive to defend such views. It is not moral cowardice, but simply absence of sufficient evidence and study of cases that prevents many physicians from urging that inebriety is

always a disease. While they are personally convinced of the truth of this fact, a public defence of it must be from clinical study, and evidence that requires time and effort to obtain. The frequency of these cases, and the general ignorance of their nature and character at present, will be a cause of great wonderment in the future.

The blundering efforts of law and religion are most disastrous to the inebriate and his malady. Inebriety, and what to do with the inebriate, is a purely physical problem which only physicians are capable of determining. The inebriate is a literal lunatic, flitting up and down the border-land where the twilight and night of mental darkness unite. Like the lunatic, the malady from which he suffers may only affect some parts of the brain, giving the appearance to the casual observer of strength to control and ability to realize all the relations of life. Hence he is always under a mask, which his disordered impulses are ever ready to maintain. Delusions of capacity to stop the use of spirits any time follow to the end of life.

The inebriate is not an enemy of society or civilization, but the victim of physical conditions—a child, a sick man, a ward of the State, needing physical care and treatment to be helped back to health and his natural place in society. To-day he is separated by a great gulf from rational recognition and treatment, and physicians only can cross this space and solve the problem. The physician should study the inebriate and define his disorder, the nature and degree of his rights and responsibility, as well as the means to remedy and remove his malady. Inebriety is not a vice or crime, but a disease to be cured by treatment. How this statement can be made an apology for inebriety and so become a *nightmare* of objection to any one, is difficult to understand. The fact that inebriety is a disease increases the responsibility of the victim and both his friends and the community to use the means for recovery. To call small-pox a disease is no apology for the victim or lessening of responsibility to use all means for restoration. To call a man insane gives no encouragement to insanity, or renders him less amenable to exact, rational treatment. In this shadowy territory clergymen and reformers lay down theories that are accepted as truths. But the march of science has carried this subject beyond the realm of morals and mystic remedies. The question of to-day is what shall we do? What means and remedies can we apply that will reach these cases? The physical nature of inebriety is clearly established wherever the subject is examined. The full acceptance of this fact will reveal the way by which a large percentage of these cases can be permanently restored to health and usefulness again.

OVARIAN CYST CURED BY INJECTION OF WINE.—Dr. Pedrini (*Gazz. Med. Ital. Lomb.*) gives the details of this case: The patient, thirty-nine years of age, was seized, after a day's washing in cold water, with acute pain in the abdomen. A few days afterward a small movable lump was noticed in the left ovarian region. The lump steadily and slowly increased for fourteen months, when it suddenly became much larger, threatening to prove fatal by asphyxia from the pressure it caused. The lungs were congested, with diffused bronchial catarrhal sounds, and the lower limbs were œdematous. The patient was very emaciated. A large trocar was thrust in at the lower third of a line drawn from the umbilicus to the anterior inferior iliac spine; seventy-two litres of a serous citrine-colored liquid were gradually withdrawn. A litre of white wine was then injected through the canula, and allowed to remain for an hour. There was sharp reaction and fever, which for a week imperilled the patient's life. She, however, made a good recovery and regained entirely her former good health, with no sign of the return of the tumor (after six years).

Progress of Medical Science.

PERCUSSION OF THE COLON IN DIARRHŒA.—Diarrhœa depending upon fecal accumulations in the lower bowel (*diarrhœa paradoxa*) is a well-known condition, the treatment of which by laxatives is of long-recognized utility. The diagnosis, however, between this form of diarrhœa and that other whose location is, more strictly speaking, in the small intestine, has often presented considerable difficulty. In an article upon this subject, in the *Deutsche Medicinische Wochenschrift* of February 14, 1883, Dr. Goedicke advocates the systematic practice of abdominal percussion in all cases of diarrhœa. He was led to adopt the practice in this wise: Several years before, when a young army surgeon, his suspicions were often aroused by the number of soldiers coming to him with the complaint of diarrhœa. In order to detect the malingerers, he made use of percussion of the colon, reasoning that in genuine diarrhœa the descending colon should be empty, and therefore give a tympanitic percussion note. He was surprised, therefore, to find that the contrary was usually the case. In most of the men in whom diarrhœa actually existed, as was ascertained from the reports of the infirmary orderlies, the percussion note of the descending colon was dull. The investigations now undertaken led him to the following conclusions: 1. In a healthy individual, with normal movements, if we percuss the colon, we shall find that the left iliac fossa usually gives a flatter note than the right. 2. In patients suffering from diarrhœa the greater dullness may be on either side, but is usually, in otherwise healthy persons, on the left. 3. The same condition obtains in children. 4. Whenever there is tenderness on pressure, it is found on the same side as the greater dullness. 5. The term "dullness" is to be understood as relative and not necessarily absolute, for the percussion note on both sides may be actually tympanitic if the colon be distended with gas. The author asserts that by far the more common form of diarrhœa is that excited by fecal accumulation in the large intestine. It is this variety which is characterized by increased relative dullness in the left iliac fossa, and in which opiates and astringent remedies are contra-indicated. In the other form of diarrhœa the trouble is in the upper bowel, and here the percussion note upon the right side is more dull, or less tympanitic, than that on the left. It is in these cases that the ordinary diarrhœa medicines find their application. Dr. Goedicke concludes by urging the practice of abdominal percussion in every case of diarrhœa, where possible (it is always possible in children, and it is in children that the knowledge of the true nature of the trouble is of the greatest importance). And he states his conviction that the more general this practice becomes, the less frequently will opium be employed in the treatment of diarrhœa.

SPASM OF THE GLOTTIS.—A very troublesome laryngeal spasm is sometimes provoked in sensitive subjects by local applications of irritant substances, either as liquid or powder. This spasm arises, according to Dr. Max Schaeffer (*Deutsche Med. Wochenschrift*, No. 2, 1883), by reason of a series of involuntary inspirations, so that when the trachea can contain no more, the air is forced into the œsophagus. He formerly attempted to overcome this by the induced current, but discovered by chance a much more simple and effective method. He holds the patient's mouth and nose and prevents any further inspirations. By this means he asserts that the spasm is speedily overcome.

SUBCUTANEOUS OSTEOTOMY.—Dr. Borchers has collected the statistics of sixty-one osteotomies performed upon thirty-seven patients by Dr. Von Muralt in the Eleonorenstift at Zurich, from 1876 to 1881 (*Correspondenz-Blatt für Schweizer Aerzte*). Of this number,

forty-eight operations were performed for bow-legs, and seven for knock-knees. Suppuration followed in nine cases, the balance progressing exactly as in simple fracture. There were two deaths, one from acute miliary tuberculosis, the other from a relapse of morbus coxarius following osteotomy for the correction of deformity at the hip. Esmarch's bandage was applied, and the operations were performed under antiseptic precautions. A straight incision, two-fifths of an inch in length, was made through the soft parts directly to the bone, which was chiselled completely through. The wound was not syringed out, nor was any drainage employed. The deformity was then corrected, a Lister dressing applied, and over that a plaster bandage. The limb was then elevated and the tourniquet removed. The temperature after the operation usually rose to 100° or 101° . The average length of treatment was forty days. The result of osteotomy for rachitic curvatures was in every case favorable. In genu valgum, tibial osteotomy was performed, as the principal deformity affected that bone. The results, as regards reduction of deformity and restoration of function, were good. The author thinks the operation is justifiable in all cases of rachitic deformity of the lower extremities in which hardening of the bones has taken place.

DENTAL FORMATION IN THE NASAL CAVITY.—Dr. Max Schaeffer relates the following case in the *Deutsche Med. Wochenschrift*, No. 2, 1883: A gentleman had for some time experienced a slight obstruction in one nostril. Examination revealed the presence of a hard, roundish, movable body, which was attached to the floor of the nostril about one inch from the anterior opening. It was removed by the snare, and was found to be a perfectly formed canine tooth, a little over an inch in length. The anterior portion was covered with enamel, and its little root presented a layer of cartilage. There was no bony alveola. The patient had all his teeth.

PERMANENT ASTHMA.—Professor Germain Sée does not accept the generally received notion of asthma as being always manifested by paroxysms of short duration, but holds that it is also met with as a disease characterized by permanent dyspnoea. He regards asthma, whether paroxysmal or permanent, as a condition made up of three elements—nervous, catarrhal, and emphysematous, either one of which may predominate and give its characteristic to the disease. It is when the latter element, emphysema, assumes an undue degree of prominence that we have the condition which the author denominates permanent asthma. It corresponds to what Waters, in his work on emphysema, characterizes (erroneously, according to Professor Sée) as primary idiopathic emphysema. This distinction which the author seeks to establish between emphysema and emphysematous asthma is, he asserts, of great importance in determining the proper treatment. His method, for which he claims excellent results, consists in the exhibition of full doses (thirty to forty-five grains per diem) of iodide of potassium. Under its continued use for some length of time, the asthmatic exacerbations disappear and the permanent dyspnoea is greatly lessened, if not entirely controlled. It is sometimes useful to add from three-fourths to one and one-half grain of opium to the daily dose of the potassium salt, to prevent iodism.—*L'Union Médicale*, March 6, 1883.

THE ORIGIN OF RESPIRATORY MURMURS.—Chomikoff and Kotovshchikoff having repeated the experiments of Aufrecht and Halbertsma, and completed a series of experimental researches of their own, conclude as follows: 1. Aufrecht's theory is incorrect; that is, the bronchial respiratory murmur does not in the least depend upon the movements of quiescent air-columns within the lung. 2. The bronchial murmur originates exclusively in the larynx; the friction of the air against the walls of the large bronchi does not give rise to these

sounds. 3. The vesicular respiratory murmurs are of a compound nature. A large part of them have a laryngeal origin; that is, the bronchial murmur originated in the larynx, while passing through the normal tissues of the lungs, changes its characters, and is heard on the lung-surface as a vesicular murmur. The remaining part of the vesicular sounds originates on the periphery of the lung, but the authors are not as yet able to elucidate its mechanism.

A NEW FUNCTION OF THE SEMICIRCULAR CANALS.—A new function of the semicircular canals has been recently suggested by Dr. M'Bride of Edinburgh (*Lancet*, February 17, 1883). The connection of these canals with the organ of hearing has been a constant enigma to modern physiology, which can discern in them no other end than that of subserving the maintenance of equilibrium and giving information as to the position and movements of the body. This function could, it is suggested, be as well performed if the canals had no relation to the organ of hearing. Their relation to it implies that they have some other function, and this Dr. M'Bride believes is to produce, through the ampullar nerves, reflex rotation of the head and eyes toward the point from which a sound proceeds, and, further, to co-ordinate and brace the muscles necessary for escaping from a danger of which sound is the first indication. The theory is, from its anatomical basis, necessarily insusceptible of direct proof. It is, however, known that irritation of the canals causes movement of the head and eyes toward the side irritated; and in pigeons a loud sound, as a pistol-shot, will cause a rotation of the head. But the effect of the discharge of a pistol is scarcely comparable to those sounds which are the usual stimuli to the auditory apparatus. The reflex phenomena produced by a sound in an uninjured animal may be equally well explained by the hypothesis that the afferent impression is through the cochlear part of the auditory nerve. At any rate, the experiments of Ferrier seem to show that when the cerebral centres of hearing are destroyed, reflex movements can only be evoked by loud sounds made close to the animal—a fact which renders it probable that the apparently reflex movements which are produced in the normal state by slight sounds are the result of true auditory sensation.

HOW TO GIVE SANTONIN.—Lewin finds fault with all the usual methods of administering santonin. According to him it should be given in its least soluble form, *i.e.*, in that form in which it will be the least readily absorbed, as the effect desired is not a general, but a local one. An oily solution of santonin undergoes, according to his experiments performed on animals, not the slightest absorption in the stomach, so that under no circumstances is any trace found in the urine. Almost any kind of oil may be employed, cocoa-nut oil, olive-oil, cod-liver oil, or castor-oil. He recommends that three grains of santonin be mixed with two ounces of oil and given in four doses. He thinks that a useful addition to the above would be that of an oil contained in santonica, the *oleum cinæ æther.*, for the reason that all ethereal oils have been shown to act as poisons on the lower forms of animal life.

THE CAUSE OF HYSTERICAL TYMPANITES.—Ebstein regards the rapidly developed tympanites in an hysterical attack as due to incontinence of the pylorus. In this way the air which is swallowed during the attack passes directly through the stomach into the intestines. In two cases in which this phenomenon was observed the distention of the entire abdomen was greatly increased immediately upon the introduction into the stomach of an effervescent mixture. The author regards this insufficiency as a pathological condition, although Kussmaul asserts that a relaxed pylorus is the normal state when the stomach is empty.—*Centralblatt für Klinische Medizin*, March 31, 1883.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 19, 1883.

DELEGATES TO THE AMERICAN MEDICAL ASSOCIATION.

WE have received several inquiries concerning the number of delegates which county societies are entitled to send to the American Medical Association. According to the plan of organization (see "Transactions American Medical Association," vol. xxxiii., p. 618) "each State, county, and district medical society, entitled to representation, shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number; provided, however, that the number of delegates from any particular State, Territory, county, city, or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of this Association."

According to the by-laws of the Association all societies entitled to representation have adopted its Code of Ethics, and therefore the members of these several societies have signed the Code of Ethics of the American Medical Association. The number, then, is left, practically, as given in the first clause—"one delegate for every ten of its regular resident members," etc.

The number of delegates, therefore, from the county and district medical societies in this State, entitled to representation, may be very large. For example, a society which has adopted the Code of Ethics of the American Medical Association, and can send delegates to the State Medical Society, may send fifty delegates if it has a resident membership of five hundred. Will the delegates be admitted? Presumably, if there is no evidence that the society which they represent has "intentionally violated or disregarded any article or clause of the same" (that is, the Code of Ethics of the American Medical Association). The question, however, has not yet been acted upon by the Judicial Council.

SUDDEN DEATH DUE TO CEREBRAL INHIBITION.

UNDER the name of inhibition, Dr. Brown-Séquard designates the arrest or suspension of function in a nervous centre, muscle, or nerve—an arrest which takes place without visible organic change, following immediately upon irritation of some point of the nervous system more or less distant from the part in which the effect is observed. It is to cerebral inhibition that the author attributes a form of sudden death, called formerly by him death without agony, which is analogous to the sud-

den loss of intellectual activity that occurs in epilepsy. This death is easily produced in animals by a simple prick of the ventricle of Arantius in the floor of the fourth ventricle. The animal falls motionless at once with complete loss of consciousness. The heart continues to beat, but respiration is arrested. The reflex action of the cord is increased. The cause of death is nowhere apparent. At least, there are no visible changes to account for it. In the absence of any other explanation, Dr. Brown-Séquard arrives at the conclusion that loss of cerebral function and activity, in certain cases, is the pure effect of inhibition proceeding from some more or less distant irritation.

THE END OF THE DEBATE IN THE ACADEMY OF MEDICINE OF PARIS.

FOR six months the learned members of the Academy of Medicine of Paris have been discussing the question whether typhoid fever should be treated by cold baths, by quinine, by salicylic acid, by carbolic acid, or should not be treated at all. The debate was brought to an end, on April 24th, by M. Peters, who summed up, in a somewhat pessimistic spirit, the results of the long battle of words.

It has been shown, he said, that we possess no specific treatment for typhoid fever, but that this disease is to be treated symptomatically in accordance with the indications.

This appears to be a small result, truly. Almost any intelligent American physician would have said the same last December before the debate began. Yet the influence of the discussion may prove useful in checking the ardor of those physicians who imagine that in cold water or carbolic acid they have at last found something which is really applicable to, and efficient in, all cases. In other words, the debate has given strength to the rational therapeutics of the disease. Nor need any one say that because there is no specific for typhoid fever, the physician cannot do much in the way of treatment. There are, on the contrary, few diseases in which intelligent watchfulness and care are so likely to prove helpful.

M. Peters, in concluding his speech, replied to Pasteur—who was absent. The speaker reiterated his former charges regarding the uncertainty, inutility, and danger of animal vaccinations by the Pasteur method. We need not go over his arguments, however, since no new facts of consequence were presented. The question at issue must be settled by practical tests in the laboratory and on the farms.

THE COMING MEETING OF THE AMERICAN MEDICAL ASSOCIATION.—Dr. X. C. Scott, of Cleveland, O., Chairman of the Committee of Arrangements, desires us to make the following announcement:

The next annual meeting of the American Medical Association will be held in Cleveland June 5th to 8th inclusive. All railroads west of Pittsburg, Salamanca, and Buffalo, east of Chicago, and south of Cleveland, will carry delegates, and members of their families, at one full fare, and return them on certificate signed by me as Chairman of the Committee of Arrangements (certifying that they have been in attendance at the meeting of the Association) at one cent per mile.

The Trunk Lines east of Buffalo, Salamanca, and Pittsburgh, and lines west of Chicago, have refused to make any reduction. The rates per diem at the hotels will be : Kennard House, \$3.00 ; Weddell House, \$3.00 ; Forest City House, \$2.50 to \$3.00 ; American House, \$2.50 ; Hawley House, \$2.00 ; Striebing House, \$2.00 ; Clarendon House, \$2.00 ; and Prospect House, \$2.00.

THE FIFTH ANNUAL CONGRESS OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, which meets in this city May 21st, 22d, and 23d, has a very elaborate programme laid out. On the first day seven papers will be read, on the second day seven, and on the third day eight. Among the more novel subjects to be treated of are : Chorea of the Larynx, Photographing the Larynx, Smell Hygienically and Medico-Legally Considered, Reflex Phenomena of Nasal Disease, Researches on the Tension of the Vocal Cords.

The Annual Dinner will be given at Delmonico's on the evening of May 21st, and there will be a theatre party and supper the next night.

Reports of Societies.

MEDICAL SOCIETY OF WEST VIRGINIA.

Sixteenth Annual Meeting, held at Grafton, West Virginia, May 16 and 17, 1883.

(By Telegraph to THE MEDICAL RECORD.)

THE sixteenth annual meeting of the Medical Society of West Virginia convened in the court house, in Grafton, W. Va., at two o'clock, on Wednesday, May 16th, the President, DR. W. B. ALLEN, of Morgantown, in the Chair.

Prayer was offered by the Rev. F. P. ROBERTSON, of the Baptist Church, in Grafton. The roll, called by DR. S. L. JEPSON, of Wheeling, the Secretary, was answered by twenty-seven members. The

ADDRESS OF WELCOME

was delivered by DR. A. L. GRANT, of Grafton, the chairman of the Committee of Arrangements, and the Hon. J. W. MASON welcomed the delegates on the part of the citizens. Dr. R. B. Stover, of Richmond, Va., and Drs. J. F. Baldwin and H. G. Landis, of Columbus, O., were recognized by the Society as delegates from sister societies. Dr. J. F. Baldwin replied to his acceptance at some length, congratulating the Medical Society of West Virginia on its State Board of Health.

ADDRESS OF THE PRESIDENT

DR. B. W. ALLEN, of Morgantown, the President, read an address touching on many matters, but referring particularly, and with some severity, to

THE RECENT BREAK IN THE MEDICAL PROFESSION IN THE STATE OF NEW YORK.

He also referred to the

NEGLECT IN THE PRELIMINARY MEDICAL EDUCATION OF YOUNG PHYSICIANS,

as evinced by the prevalence of several epidemics of small-pox throughout the State. He advocated, with much ability, the creation and sustenance of a medical department in the University of the State of West Virginia, at Morgantown.

DR. J. E. REEVES, of Wheeling, called the attention of the Society to the fact that a ruling, at one of its early meetings, prevents the election of a man to the State Society unless in good standing in his County Medical Society. He thought this ruling very unjust and, after argument, moved that the former resolution be repealed.

DR. G. BAIRD, of Wheeling, also spoke against the

old ruling, which was sustained in quite an animated speech by DR. J. M. LAZZELL, of Fairmont, who moved that DR. REEVES' appeal be laid on the table. It was, however, put to the vote and carried by the Society.

DR. R. W. HALL, of Mannington, from the

COMMITTEE ON EPIDEMICS,

reported no severe general epidemic to have existed in the State, but nearly all the epidemic diseases to be present. The paper referred to pneumonitis, naso-pharyngitis, influenza, scarlatina, rubeola, variola, varicella, pertussis, parotitis and typhoid fever, discussing all these diseases, and typhoid fever at length, strongly arguing for the contagiousness of this disease, and citing cases in support.

The discussion on the paper was opened by DR. J. S. REEVES, who recommended the use of

ERGOT AS A PREVENTIVE OF HEMORRHAGE,

and also as an antiphlogistic agent.

DR. R. B. STOVER, of Richmond, Va., had also noticed a reduction of temperature following the use of one drachm of Squibb's fluid extract of ergot, every three hours, in both pneumonia and typhoid fever.

DR. A. GERSTELL, of Keyser, thought typhoid fever a purely germ disease, which could only be taken from the introduction into the system of fecal matter.

DR. T. L. JEPSON, of Wheeling, thought that the discussion propounded three questions, which, with their answers, were as follows :

First.—May the disease arise *de novo*? The facts which he had obtained from a perusal of the report of the Massachusetts State Board of Health prove that it does.

Second.—Is it contagious? The fact that not a doctor, nurse, or patient, had been known in all his hospital practice to take disease from undoubted typhoid fever cases, proves that it is not.

Third.—What remedies are indicated? Statistics on the therapeutics of typhoid fever show the uncertainty of the action of any one reputed species. It requires a stupendous array of confirmatory cases to establish the success of any drug as a specific in this disease.

DR. J. M. LAZZELL instanced a case occurring in his own practice as going to show that typhoid fever is communicable. He had known it to occur twice in the same person.

DR. J. F. HAMILTON, of Columbus, O., spoke strongly in favor of the

DE NOVO ORIGIN OF TYPHOID FEVER.

He treated his cases with milk and lime-water.

The Secretary read his report, which was accepted. The Treasurer's report showed a balance on hand of \$115. The Board of Censors passed upon the following list of

CANDIDATES FOR ADMISSION TO THE SOCIETY.

C. F. Johnson, T. F. Landman, C. M. Frizell, A. P. Nathans, J. H. Silvey, E. M. Baird, J. L. Nixon, C. V. Henry, J. C. Lawson, and G. L. Bomberger. These gentlemen were all elected members.

THE ARMY MEDICAL MUSEUM AND LIBRARY.

DR. JAMES S. REEVES, of Wheeling, introduced the following preamble and resolutions, which were adopted unanimously by the Society, viz.:

Whereas, The collections known as the Army Medical Museum and Library of the Surgeon-General's Office, located in Washington, D. C., are recognized among the most complete and valuable of their kind in the world, and as their practical usefulness has been abundantly demonstrated by the interest with which they are regarded by the medical profession, both at home and abroad, and :

Whereas, By reason of the insecurity and unsuitability of the building in which they are now placed they are in constant danger of damage or destruction, from which would ensue irreparable loss, therefore :

Resolved, That in the opinion of the Medical Society of the State of West Virginia, the inestimable value of these

collections demands from Congress such fair consideration of the merits involved as will secure an appropriation of sufficient amount to provide a fire-proof building, of an ample size and suitable construction, for the present and future uses of the Museum and Library.

Resolved, That the Army Medical Museum and Library of the Surgeon-General's office are inseparable in object and interest, and only capable of the greatest usefulness when under one control and management; that this Society views with regret and disfavor any attempt to separate the two; dismemberment must result in injury to both.

Resolved, That Congress would meet the wishes of the medical profession of the United States by appropriating suitable sums of money for the support, care, and increase of the collections, viz.: not less than ten thousand dollars annually for the library, and five thousand dollars for the museum.

Resolved, That the work now in progress under the direction of the Surgeon-General of the army, entitled "An Index Catalogue of the Library of the Surgeon-General's Office," is also one in which the medical profession of the United States is greatly interested, and should receive the substantial aid and encouragement of Congress with a view to its speedy and certain completion.

Resolved, That a copy of these preambles and resolutions be forwarded to each senator and representative of our State, requesting his special aid and co-operation in the matters herein specified.

The meeting then adjourned for the day. The Rev. W. A. Shipman, of Grafton, delivered an address at 7.30 P.M. in the Court House, on "Materialism." At 9 P.M. a grand ball was tendered to the visiting physicians by the citizens.

A report of a case of

PERITONEAL HÆMATOCELE

was read by DR. R. W. HALL, of Mannington, W. Va.: Dr. G. L. McIntire, of Grangeville, W. Va., requested me to see in consultation with him Mrs. R—, stating that the patient was about thirty years of age, a multipara, and had enjoyed good health until about four weeks previous, when she had metrorrhagia and sent to Dr. McIntire for medicine. The doctor sent her the usual remedies and she was, as she thought, well in a few days. After a little more than two weeks elapsed, she became very nervous, had considerable nausea and occasional rigor. This condition continued for a little over a week, gradually getting worse, and pain was present in the hypogastrium. She became very restless, the nausea became more marked until emesis occurred. On rising one morning she observed for the first time that she had a tumor about the size of a child's head in the lower part of the abdomen. This condition caused her considerable alarm. In a few days it became very tender to the touch and she observed it to be increasing rapidly in size. She then sent for Dr. McIntire, who, thinking the case of a serious nature, requested consultation. I saw the patient Friday evening. Upon examination found tongue coated with a light fur; pulse, 90; respiration, 24; and temperature, $101\frac{1}{2}^{\circ}$. Dr. McIntire informed me that the pulse had been normal as well as the temperature up to the evening I saw the patient. I found in the hypogastrium, to the left of the median line, a round tumor about the size of a two-year old child's head, hard and exceedingly tender to the touch. A digital examination, per vagina, revealed the uterus slightly prolapsed, but no other evidence of disease. After a careful consideration of the case we diagnosed hæmatocele, and to make the diagnosis certain, we took a hypodermic syringe, pushed the needle into the tumor, and drew out some of its contents, which were fluid and had the appearance of prune-juice. Recognizing this as blood in a partial state of decomposition, the diagnosis was thus proved correct. Owing to the large quantity of fluid, we could not hope that relief would come to the

patient by nature's slow process of absorption, and to avoid the great danger feared from septicaemia, we advised the evacuation of the tumor. The patient consenting, on Sunday morning, two days later, we drew, by means of the aspirator, ninety-six ounces of fluid, resembling in color prune-juice, and having quite an offensive odor.

The patient expressed herself greatly relieved; all the tenderness and pain had vanished as if by magic. We directed that an antiseptic treatment be pursued, together with astringents, and that Dr. McIntire see the patient daily. The patient soon had general peritonitis. By Dr. McIntire's skilful management she finally recovered, and at this writing enjoys good health.

DR. D. P. MORGAN, of Clarksburg, read a paper on

THE ABUSE OF ERGOT IN OBSTETRIC PRACTICE.

The teachings of college professors and of text-books on obstetrics of how and when to give ergot in labor are various and very conflicting. One will tell us to give ergot when the pains are slow, another to give it to overcome inertia during the first stage of labor, and another that it shall never be given during the first or second stages of labor; another will tell us it is little less than murder to give it while the child is viable, another advises us to give it only to expel a retained placenta or to control post-partum hemorrhage, while still others advise us to use it only as a prophylactic against hemorrhage, or to give it to prevent after pains, etc. Now this is all confusing, more especially to the younger members of our profession, and I shall, after noticing very briefly its action on the uterus during labor, try and formulate a few rules as to when it shall not be given. Now it is desirable to ascertain, if possible, the true effects of ergot on the muscular fibres of the uterus, and on the foetus within the uterine cavity. It usually produces in a uterus at term or in labor a strong tonic contraction, which differs from the natural rhythmical contraction, which is followed by a period of relaxation, in being of a continuous or tetanic nature, and if the dose be repeated often, or a sufficient quantity given, a continuous and powerful tetanic contraction is usually produced, which is participated in by all the uterine muscular fibres, and the contents, be they fetal, placental, or blood clot, are held as in the jaws of a vice instead of being normally expelled, and thereby often proving fatal to the child by compressing the cord and thus cutting off the fetal circulation.

The so-called hour-glass contraction is evidently a form of tetanic contraction, similar to that produced by ergot. Again, the action of ergot is not uniform. It may act on a part, or upon the whole organ, it may act upon one set of the muscular fibres and not on the others. It may produce such a powerful tetanic contraction as to drive a head too large into a pelvis too small or deformed, and thus produce impaction with all its fearful consequences. It may, and has produced all the lacerations possible, from rupture of the uterus, with escape of the foetus into the abdominal cavity, to that of the perineum, with great shock, loss of blood, etc. It has produced pelvic cellulitis and peritonitis; it has produced gangrene and sloughing of all the soft tissues in the pelvic cavity. It very frequently produces laceration of the cervix uterus; it has produced such extensive sloughing of the vagina as to result in contraction, destroying the entire vaginal canal. The safety of the maternal tissues and the life and health of the child depend upon a regular relaxation after each successive contraction of the uterus, as well as the recession of the presenting foetus, and when such contraction, relaxation, or recession are replaced by a tetanic, or continuous contraction, injury to either mother or child, or both, is apt to result. And yet, in the face of all the facts, very many physicians daily use ergot without any especial object or aim as to its results, they merely feeling the necessity of giving something, or doing something. Now

I claim that in giving ergot during the first stage of labor we commit malpractice. But in what does this malpractice consist? It is this: Ever since Dr. Stearns, of Saratoga County, N. Y., in 1807, had his letter published in the *New York Medical Repository*, and even unto the present moment, many, very many physicians will attend a given case of labor, the usual examination is, or is not made, perhaps the usual inquiry as to the condition of bowels, bladder, etc., is made, how long the lady has been in pain, frequency of pains; how long intervals intervene, etc. The physician perhaps finds the os dilated as large as a twenty-five cent coin, or larger, with moderate pains and long intervals. He is in a hurry, besides he feels that he must do something, gives a teaspoonful of the liquid extract of ergot, or its equivalent of tincture, wine, or infusion, or a hypodermic injection of ergotine, waits twenty or thirty minutes, gives another dose, and another, until the uterus is thrown into a furious state of contraction, with scarcely any relaxation. The result will probably be a dead child with some one or more of the serious injuries above mentioned to the mother.

Well, when shall we give ergot in cases of labor? First, never till the uterus is thoroughly dilated or dilatable and the perineum is thoroughly relaxed and the pelvis properly shaped, and it is better not given then. Secondly, not till the head has passed the perineum and continued inertia exists. Thirdly, to secure contraction in post-partum hemorrhage, and then not till the uterus is emptied of placenta clots, etc., by other means; and in this case continued pressure over the fundus, after the method of Criede for expelling the placenta, is much better; besides, the intra-uterine injection of very hot water is superior to ergot and will not produce the nausea, vomiting, and prostration, as is frequently done by ergot. Hence ergot is not necessary at all during the first stage of labor. It should only be given in the second stage when the os uteri is dilated and the perineum relaxed, and then only in conditions of continued atony; and here abdominal bandages, stimulants, quinine, etc., will overcome this atony in almost all cases, and with much more ease, safety, and satisfaction than ergot or any similar remedy. Ergot is unnecessary in post-partum hemorrhage, except in small tonic doses of ten to twenty drops every half, one, two, or three hours, and even here we possess in the hand a safe, rational, quick, easy, ever ready remedy, to be used in the manner before mentioned. In the Bethesda Hospital, in Dublin, the use of ergot as an oxytocic before delivery has been prohibited by the trustees. Finally, it has serious disadvantages and it is very questionable whether the risks to both mother and child do not more than counterbalance any advantages attending its use, or, in other words, it were probably better that it had never been given in labor before the uterus was emptied.

The second day's session convened in the Court House at 8.30 A.M.

ENDORING THE CODE OF THE AMERICAN MEDICAL ASSOCIATION.

Immediately after the offering of prayer the following preamble and resolutions were moved by DR. D. H. MORGAN, of Clarksburg:

Whereas, The medical profession of West Virginia views with deep concern and regret the confusion and discord which have resulted in the State of New York from the action of the State Medical Society in renewing allegiance to the code of ethics of the American Medical Association, under which all State and other auxiliary societies have so long and harmoniously worked together for the common good; and

Whereas, Certain medical journals and specialists, under the specious plea of "liberality," humanity, and advancing civilization, have used and are still using every effort to bring about and maintain such a degree of opposition to the National Code as shall completely

separate the said State Medical Society of New York from affiliation with all loyal organizations in other States, thus rendering it independent of and antagonistic to the American Medical Association; therefore

Resolved, That the Medical Society of the State of West Virginia again declares and reaffirms its willing allegiance to the time-honored notion and code of medical ethics as the great common law, and the only safe and proper guide for the physician in the midst of the conflicting interests with which he is beset in daily practice and in his interests with his fellows.

Resolved, That the delegates from this society to the American Medical Association, at its forthcoming meeting, be and they are hereby instructed to resist, by their votes and influence, all attempts which may be made to change or modify any of the provisions of the code, or to in any other way compromise the dignity, standing, and influence of the profession.

Resolved, That this Society recommends to the medical profession of West Virginia, that they support, by their subscriptions, only such medical journals as recommend their patients to such specialists, and direct their students only to such medical colleges as have shown, by their unequivocal attitude, their representation, the demands of true humanity, their recognition of the pure and unselfish aspirations of our calling, and their loyalty to the high and noble interests of rational medicine.

Resolved, That a copy of these preambles and resolutions be forwarded to the Permanent Society of the American Medical Association.

The resolution was unanimously adopted.

A JOURNAL FOR THE SOCIETY.

The following was then read:

Whereas, The Medical Society of the State of West Virginia is growing in numbers and increasing in usefulness, as is evidenced by the superior quality of the papers, so far read, and by the interest manifested on medical subjects generally in the State, and

Whereas, Our State has a law regulating the practice of medicine, and establishing a State Board of Health which is not surpassed, if even equalled, by any similar law in any of the States, and

Whereas, The Society, and the profession at large in the State have no medium of communication on medical and public health subjects, except the annual meeting of the Society;

Whereas, The State Board of Health and the Medical Society should be in perfect harmony and be enabled to interchange opinions and suggestions upon public health subjects, therefore be it

Resolved, That this Society elect annually three members, which shall constitute a Committee on Publication, whose duty it shall be to associate with themselves an editor, which committee and editor shall publish a quarterly medical journal under the auspices of this Society, and, if practicable, in conjunction with the State Board of Health, which committee and editor, in addition to publishing through the different numbers of the journal (after being approved, passed, and read before this Society), may insert original articles, reports of cases, communications, selections, translations, medical and sanitary news, etc.

DR. J. M. LAZZELLE, of Fairmont, spoke against this plan, as did also DR. J. FRIZELLE, of Wheeling. Moved to be referred to the Committee on Publication. Carried.

MR. F. HOWELL, of Clarksburg, read a report of a

CASE OF ESOPHAGOTOMY FOR THE EXTRACTION OF A SILVER FIFTY CENT PIECE

swallowed, by recovery, with suggestions as to the conditions under which the operation is justifiable.

The following conclusions were reached by the author, First, when a foreign body has become lodged in the

"cervical" portion of the "oesophagus," and has resisted a fair trial for its extraction or displacement, its removal should be at once affected by incision. Second, when a foreign body has become lodged in the "oesophagus," determinable within a finger's length below the upper end of the "sternum," and has resisted a thorough trial for its extraction or displacement, its extraction should be at once attempted by incision. Third, when a foreign body has become lodged in the "oesophagus" at a point beyond a finger's length below the upper end of the "sternum," or in extreme cases, even at the cardiac contraction, and its position can be pretty definitely ascertained, and its character, size, shape, etc., are known or have been pretty definitely determined to be such that it could not, without great danger, work its way outward, or pretty readily become dislodged or loosened by ulceration and pass onward, and it has resisted the most careful and thorough efforts for its extraction or displacement, its extraction should then be at once attempted by an operation.
